Chemical compounds released from an individual capable of modifying the behavior of another individual who perceives them are generally defined as semiochemicals (Regnier, 1971). They can be further subdivided according to their function either between individuals of the same species (i.e., intraspecific) or separate species (i.e., interspecific).

In intraspecific communication, chemical signals exchanged between conspecific individuals are generally defined as pheromones (Karlson and Lüscher, 1959), fundamental elements in sexual communication typically functioning to attract conspecific mating partners (e.g., Baker, 1989; Wyatt, 2003) and to signal fertility, reproductive status, and mate quality (e.g., Hardie and Minks, 1999; Johansson and Jones, 2007). Although females have long been assumed to be the main emitters of sex attractants (Antony and Jallon, 1982; Löfstedt, 1993; Wyatt, 2003), more recent studies have delivered empirical evidence that males are not mostly restricted to the role of receivers, but can be sex attractant emitters as well (Grillet *et al.*, 2006; Ruther *et al.*, 2007; Eltz *et al.*, 2008). Independent of which sex is emitter or receiver, both parts of the communication system are required to be tightly coordinated to ensure accurate and successful mutual attraction of the mating partners (Bargmann, 2006).

Semiochemicals used in interspecific communication are generally defined as allelochemicals (Nordlund and Lewis, 1976; Dicke and Sabelis, 1988), and can be further subdivided into three main types: kairomones, allomones, and synomones (Brown *et al.*, 1970; Regnier, 1971). Those benefitting the receiver, while usually putting the sender at a disadvantage, are commonly defined as kairomones; whereas the ones benefitting the sender through behavioral modification of the receiver, while having a neutral or disadvantageous effect on the latter, are known as allomones. Synomones, on the other hand, are semiochemicals that benefit both the sender and the receiver (Brown *et al.*, 1970; Regnier, 1971). Semiochemical parsimony refers to the phenomenon when

a particular semiochemical simultaneously fulfills several of the above-mentioned categories depending on the specific behavioral context induced in several different recipients. For instance, an intraspecific sex pheromone may also function as a kairomone luring a predatory species in addition to a conspecific mate (Gullan and Cranston, 2010; Matthews and Matthews, 2010).

The phenomenon and terminology of kairomones, in general, represents an interesting evolutionary conundrum: It has been argued that a semiochemical mediating an interaction that is ultimately detrimental to the emitter would be selected against (Blum, 1977; Dicke and Sabelis, 1988). However, if put into perspective, it appears to be important to take the benefit into account that the emitter might gain, and weigh it against the potential detrimental effect when it is interspecifically exploited as a kairomone (Nordlund and Lewis, 1976; Weldon, 1980). A well-investigated case study constitutes the aggregation pheromone of bark beetles, which are important and beneficial in intraspecific calling behavior to quickly exploit food sources and potential mating grounds, while simultaneously bearing the risk of interspecific interception by predators (Wood, 1982).

Allomones, on the other hand, benefit just the receiver, and thus provide a strictly one-sided selective advantage. Bolas spiders of the genus *Mastophora* provide an excellent example for this: Specialized to prey on male moths, female bolas spiders use a specific string of web with a ball of glue at the distal end, which they actively swing towards their prey in flight (Eberhard, 1977; Yeargan, 1988). Most strikingly, it has been shown that bolas spiders produce compounds identical to the female moth sex pheromones that they instill on their bolas, an allomone through chemical mimicry by definition (Stowe et al., 1987; Haynes and Yeargan, 1999).

A case-in-point study exemplifying the definition of synomones would be volatiles released by leguminous plants that are damaged by feeding and oviposition activity of the southern green stink bug (*Nezara viridula*). These volatiles, in turn, attract the egg parasitoid wasp *Trissolcus basalis* (Wollaston), a highly efficient natural enemy of *Nezara viridula* whose own larvae parasitize and eventually consume the eggs of the southern green stinkbug laid previously on the plants (Hoffmann et al., 1991; Ehler, 2002; Colazza et al., 2004). Thus, both the damaged plants as well as the parasitoid wasps benefit from the emitted volatile plant synomones (Colazza et al., 2004).

Interactions of Different Signaling Modalities

Though integrative empirical studies assessing and incorporating different communication modalities are relatively rare, several case studies provide intriguing examples on how various signaling modalities can interact for optimizing information transfer.

In certain species of the aforementioned fireflies, it has been shown that, although visual communication is used for long-range mate attraction through bioluminescent flashing signals, close-range mate and species assessment can be mediated through olfactory communication via contact sex pheromones in certain species (South et al., 2008).

Similarly, field crickets, a prime example of long-distance mate attraction through auditory signaling, have been shown to incorporate olfactory signaling in their sexual communication behavior as well. Thus, female crickets, attracted through male mate calls, have been shown to use chemical cues to preferentially mate with novel males (Ivy et al., 2005), to favor unrelated males (Simmons, 1991), and to discriminate dominant from subordinate males (Kortet and Hedrick, 2005).

Nest-founding females of the paper wasp, *Polistes dominulus*, are apparently capable of discriminating different shapes, numbers and sizes of black facial spots on their rival foundresses to assess their quality, but chemical contact pheromones have also been shown to play a crucial role in their nestmate recognition behavior (Dani et al., 2001; Matthews and Matthews, 2010).

In *Drosophila* fruit flies, all three main signaling modalities apparently play a role in their complex courtship and mating behavior, as visual, acoustic, and chemical signaling have all been shown to contribute to mate localization, assessment, and acceptance (Cobb and Ferveur, 1995; Greenspan and Ferveur, 2000; Marcillac and Ferveur, 2004).

A quite unique case of a different and unusual signaling behavior has been found in honey bees: First decoded over 70 years ago by Karl von Frisch, honey bees have evolved a complex 'dance language' to convey information about the location of distant food sources to their nestmates (von Frisch, 1946). This well-known behavior constitutes a characteristic figure eight shaped 'waggle dance' that returning scouting bees perform on the vertical wax combs inside the bee hive (von Frisch, 1946, 1967). Thus, information about the distance of a new food source is conveyed by the duration of the 'waggle phase' of the dance, whereas information of the direction of the food source is based on the orientation of the dancer's body position relative to gravity (von Frisch and Jander, 1957; Gould et al., 1970; Riley et al., 2005). This signaling behavior is apparently complemented with auditory cues providing additional and more complete information about the distance of potential food sources from the hive (Wenner, 1962).

Furthermore, particularly fascinating examples of combinations of communication modalities include cases where larger taxonomic boundaries are traversed between very different species. For instance, certain lepidopteran larvae and pupae show functionally similar acoustic communication patterns to their symbiotic ant hosts, although their respective calls are apparently produced by very different means (Devries et al., 1993; Travassos and Pierce, 2000; Barbero et al., 2012). Even larger taxonomic boundaries are bridged in warning coloration arms races between certain butterflies and their vertebrate predators, e.g., bats (Dunning et al., 1992) or birds (Endler and Mappes, 2004; Langham, 2004), not to mention the well-known mutualistic visual and olfactory communication between plants and their insect pollinators (e.g., Silberglied, 1979).

Outlook

Despite a handful of intriguing case studies, integrative investigations of different communication modalities are still mostly lacking, and bear huge potential for unraveling a more holistic view on the entire spectrum of signaling interactions. For instance,

in the Hymenoptera (ants, bees, and wasps), one of the most prominent and largest insect orders (Grimaldi and Engel, 2005; Sharkey, 2007), studies on auditory communication are woefully absent so far (Claridge, 2005). Also, in more general terms, insect auditory communication has only occasionally been studied in interspecific interactions, particularly predator-prey and parasite-host relationships. However, integrating auditory with other communication modalities would greatly aid our understanding of how different information transfer modes interact to provide the full sensory spectrum in signaling relationships (Claridge, 2005). With the vast technological advancements in recent decades, our ability to record, analyze, reproduce, and synthesize different types of conveyed information has been greatly augmented. Therefore, combining our knowledge from these very different fields could open up new and exciting venues in deciphering insect communication in all its fascinating aspects.

Migration and Navigation in Fish

Migratory Fish

Among the roughly 30,000 species of fish, migratory species account for only 165 species. However, they show interesting and complex life histories, and acquire many important biological functions that make possible for successful migration and navigation. Moreover, most of migratory fishes are valuable fisheries resources. Migratory fish either alone or in schools make drifting migration from spawning area to nursery area for recruitment, feeding migration from nursery area to feeding area for growth, and spawning migration from feeding area to spawning area for reproduction (Fig. 1). In special case, drifting migration occurs again from spawning area to feeding area if adults could survive after reproduction. Some migratory fishes are semelparous species that all adults die after reproduction only one time for their lifetime (semelparity), and other migratory fishes are iteroparous species that adults produce offspring several times during their lifetime (iteroparity). These migrations form a migration loop to produce next generations continuously, and allow fishes not only to exploit different food availabilities and to adapt to environmental changes, but also to regulate population density and widen their distribution.

Classification of Fish Migration

Migratory fishes are classified into the diadromous species that migrate between freshwater and seawater, and the non-diadromous species that migrate either only in seawater or freshwater (Table 1). The diadromous species are divided into catadromous species (eel), anadromous species (salmon, sturgeon, American shad, and striped bass), and amphidromous species that is further divided into seawater species (Japanese sea bass) and freshwater species (ayu). These migrations are characterized by their hatching, growing, and spawning area in either freshwater or seawater. Amphidromous fishes that are special species of catadromous and anadromous species can grow both in freshwater and seawater (Fig. 2). The non-diadromous species are divided into oceanodromous species that are further divided into highly migratory species (tuna) and coastal migratory species (herring), and potamodromous species that are further divided into fluvial species (Mekong giant catfish) and lacustrine species (isaza) (Table 1). Some migratory species have amazing abilities to precisely migrate and navigate thousands of kilometers from their feeding area to their natal spawning area, and anadromous salmon is famous for its accurate homing to the natal spawning area in the rivers. Other migratory species have relatively wide spawning areas. Each typical fish migration is reviewed using representative species.

Catadromous Migration

Eel is a worm-water catadromous species, and divided into four species: American eel (*Anguilla rostrata*), European eel (*A. anguilla*), Japanese eel (*A. japonica*), and short-finned eel (*A. australis*). They begin their life in the ocean as larval form called “leptocephalus” that drift with the aid of the ocean current toward the estuaries of continental shelf where they metamorphose into transparent larval stage called “glass eels.” Many of glass eels make upstream migration into freshwater habitats where they grow into “yellow eels” for 5–20 years, and some become “sea-eels” that never enter freshwater spending their entire lifetime in the ocean (Tsukamoto *et al.*, 1998). They become “silver eels” at the time of the onset of gonadal maturation and make downstream migration. Adult eels make oceanic spawning migration to the spawning area, and all adults die after reproduction (semelparity).

Fig. 1 Fish migration showing migration loop. Modified from Ueda, H., Tsukamoto, K., 2013. Physiology and Ecology of Fish Migration. CRC Press, Taylor & Francis Group. ISBN 978-1-4665-9513-2.

Table 1 Classification and representative species of migratory fish.

I. Diadromous species	
1. Catadromous species:	Eel
2. Anadromous species:	Salmon; Sturgeon; American shad; Striped bass
1) Sea-run form	
2) Reident form	
3. Amphidromous species	
1) Seawater species:	Japanese sea bass
2) Freshwater species:	Ayu (Sweet fish)
II. Non-diadromous species	
1. Oceanodromous species	
1) Highly migratory species:	Tuna
2) Coastal migratory species:	Herring
2. Potamodromous species	
1) Fluvial species:	Mekong giant catfish
2) Lacustrine species:	Isaza

Fig. 2 Diadromous fish migration showing catadromous specie (eel), anadromous species (salmon), and amphidromous seawater species (Japanese sea bass) and freshwater species (ayu).

European eel

The spawning areas of European eel was found in the Sargasso Sea in 1920s, but many mysteries of juvenile and adult migration between the Sargasso Sea and freshwater habitats distributed along European countries are unsolved yet. Juveniles were reported to possess a magnetic map of the North Atlantic Ocean and use to target the Gulf Stream System (Naisbett-Jones *et al.*, 2017). The spawning migration of adults were observed by biotelemetry techniques revealing that they exhibited diel vertical migrations in deeper water during the day and shallower water at night at the swimming speeds from 3 to 47 km/day (Righton *et al.*, 2016).

Japanese eel

The spawning area of Japanese eel was discovered in the west of the Marian Islands where adults and newly hatched larvae were caught during new moon periods throughout the spawning season indicating that spawning occurs in shallower layers of 150–200 m (Tsukamoto *et al.*, 2011). However, there are many mysteries about how can adult eel migrate and navigate in ocean and find their spawning site using what kinds of sensory systems.

Anadromous Migration

Salmon is a cold-water anadromous species, and divided into Pacific salmon (genus *Oncorhynchus*) and Atlantic salmon (genus *Salmo*). There are seven Pacific salmon species and two Atlantic salmon species, and they show different complex life cycles.

Pacific salmon

In Pacific salmon, underyearling all juveniles of pink salmon (*O. gorbuscha*) and chum salmon (*O. keta*) make downstream migration in spring within a few months after emergence, and there is no resident form. Adult pink salmon and chum salmon make upstream migration in autumn within a few weeks of spermiation and ovulation after 2 years and 2–7 years oceanic feeding migration, respectively. In contrast, juveniles of sockeye salmon (*O. nerka*), Chinook salmon (*O. tshawytscha*), coho salmon (*O. kisutch*), and masu salmon (*O. masou*) stay in freshwater rivers or lakes for a few years, carry out smoltification (parr-smolt transformation) that is physiological changes obtaining seawater adaptability, and make downstream migration in spring. There are resident individuals that spend their whole life in rivers or lakes. Adults make upstream migration after several years of oceanic feeding migration in autumn at least several months prior to spermiation and ovulation (Fig. 3).

These six Pacific salmon are semelparous species. It is phylogenetically reported that pink salmon is the most advanced salmon species, while masu salmon is the most primitive species (Murata *et al.*, 1996). Pink salmon is also the most widely distributed species in the north Pacific Ocean and have the largest population size, while masu salmon appear to have the most restricted distribution to the west Pacific Ocean and the smallest population (Kaeriyama and Ueda, 1998). Although the homing accuracy of these salmon has not been compared in detail, it is believed that masu salmon return to their natal stream with the highest precision, and that pink salmon are more likely to stray into a non-natal stream. If most salmon might show a highly accurate homing to the natal stream, there would be little chance to enhance their distribution area as well as to increase their population size. And, they might encounter the dangerous possibility to reduce their genetic diversity. The relationship between salmon evolution and homing accuracy is one of the most interesting questions from a viewpoint of biological evolution.

Steelhead or steelhead trout (*O. mykiss*) is a sea-run form of rainbow trout, and an iteroparous species. Juveniles remain in freshwater for a few years before smoltification, and migrate to ocean. Adults make upstream migration to their natal spawning areas for breeding, and about 10% of adults survive and make drifting downstream migration again from spawning area to oceanic feeding areas in multiple years.

Atlantic salmon

In Atlantic salmon (*S. salar*) and sea trout (*S. trutta*) that is a sea-run form of brown trout, juveniles stay in freshwater for several years, and grow to smolt that make downstream migration to ocean where they do feeding migration for several years. There are some resident individuals that never enter to seawater spending their entire lifetime in freshwater. Adults make upstream migration to their natal spawning areas for breeding, and some can survive after spawning and make drifting downstream migration again from spawning area to oceanic feeding area in multiple years (Iteroparity).

The other anadromous species

The other anadromous species include sturgeon (four genera: *Acipenser*, *Huso*, *Scaphirhynchus*, and *Pseudoscaphirhynchus*), American shad (*Alosa sapidissima*), and striped bass (*Morone saxatilis*). They all spawn in freshwater, make downstream migration into seawater where they grow, and make upstream migration for reproduction.

Fig. 3 Life history of two different types of Pacific salmonid species. Dotted line: chum and pink salmon; Solid line: sockeye, Chinook, coho and masu salmon. Ueda, H., Tsukamoto, K., 2013. Physiology and Ecology of Fish Migration. CRC Press, Taylor & Francis Group. ISBN 978-1-4665-9513-2

Amphidromous Migration

Seawater species

Japanese sea bass (*Lateolabrax japonicus*) is a seawater species of amphidromous fish, native to the west Pacific Ocean, and spawn in coastal sea in winter. Juveniles inhabit in seawater, brackish water, and freshwater where they grow from spring to autumn, and make upstream migration in rivers to avoid high water temperature. Adults make downstream migration to coastal sea for reproduction.

Freshwater species

Ayu or sweetfish (*Plecoglossus altivelis*) is a freshwater species of amphidromous fish, and spawn in rivers in autumn. Juveniles make drifting downstream migration to coastal sea where they feed planktons in winter. Young fish make upstream migration in the lower and middle reaches where they feed attached algae, spawn in autumn, and die after reproduction (semelparity).

Oceanodromous Migration

Highly migratory species

Tuna is divided into true tuna species (genus *Thunnus*) and other tuna species (four genera: *Allothunnus*, *Auxis*, *Eurhynchus*, and *Katsuwonus*). The genus *Thunnus* is further divided into two subgenera: the bluefin group and the yellowfin group. There are five species of relatively large size bluefin group: albacore tuna (*T. alalunga*), southern bluefin tuna (*T. maccoyii*), bigeye tuna (*T. obesus*), Pacific bluefin tuna (*T. orientalis*), Atlantic bluefin tuna (*T. thynnus*), and three species of relatively small size yellowfin group: blackfin tuna (*T. atlanticus*), longtail tuna (*T. tonggol*), yellowfin tuna (*T. albacares*).

Tunas are endothermic species that can maintain their body temperature of certain parts of body (skeletal muscles, eyes, and brain) above the temperature of ambient seawater, which supports faster swimming speeds (up to 75 km/h) and survival in cooler ocean environments. They distribute throughout the oceans of the world, generally in tropical and temperate waters at latitudes ranging between about 45° north and south of the equator. They carry out migrations of significant distances across oceans for feeding and reproduction. They are iteroparous species, and their relatively large spawning areas in the ocean are different among species.

Coastal migratory species

Herring is divided into three species: Arucanian herring (*Clupea bentincki*), Atlantic herring (*C. harengus*), and Pacific herring (*C. pallasii*). They make migration in school from open ocean to coastal sea in intertidal and sub-tidal environments, and spawn in variety seawater environments at different seasons among species. Eggs are laid on the seabed (rock, stones, gravel, sand) or submerged vegetation (eelgrass or seaweed), stick in layers of clumps to gravel, seaweed, or stones.

Potamodromous Migration

Fluvial species

Mekong giant catfish (*Pangasianodon gigas*) is a critically endangered species and native to the Mekong basin. They are recognized as the world's largest freshwater species weighting up to 350 kg. Although little is known about their migrations in the Mekong River, they congregate during the beginning of the rainy season and migrate upstream to spawn in the Mekong River.

Lacustrine species

Isaza (*Gymnogobius isaza*) is an endemic species in Lake Biwa, Japan. They are freshwater pelagic species, inhabit offshore areas in the lake, and migrate to the shore to spawn under stones in spring. Males care for the eggs in their nest.

Physiological Mechanisms of Migration and Navigation in Fish

Migratory fishes possess many important essential biological functions that make possible for a long distance migration and navigation between their nursery habitats, feeding habitats, and spawning habitats in their complex life histories. Especially, salmon are recognized for their amazing abilities to memorize their natal river information during downstream migration, carry out thousands kilometer feeding migration in the ocean for many years, and make homing migration precisely to their natal rivers for reproduction. Physiological mechanisms of imprinting and homing migration of Pacific salmon were reviewed using three different research approaches: Homing behavior of adult chum salmon from the Bering Sea to Hokkaido as well as lacustrine sockeye salmon and masu salmon in Lake Toya (serves as a model ocean) were examined using physiological biotelemetry techniques; Hormone profiles in the brain-pituitary-thyroid (BPT) and brain-pituitary-gonad (BPG) axes of chum and sockeye salmon were analyzed using endocrinological techniques; Olfactory memory formation and retrieval of natal stream odors in Pacific salmon were investigated using neurobiological techniques (Ueda, 2016). Finally, impacts of global climate changes on these physiological mechanisms of migratory fish are reviewed.

Physiological Biotelemetry Researches on Adult Salmon Homing Migration

The recent rapid development of biotelemetry technologies, such as ultrasonic and radio telemetry, data logging, and pop-up satellite telemetry, makes it possible to continually observe the underwater behavior of migratory fish in open water (Hussey *et al.*, 2015). Japanese adult chum salmon homing behavior from the central Bering Sea to the east coast of Hokkaido, Japan was examined using propeller data loggers, which recorded swimming speed, depth, and temperature (Tanaka *et al.*, 2005). The first recorded swimming profiles of homing chum salmon in the oceanic phase revealed that chum salmon had travelled with an average swimming speed, depth, and temperature of 62 ± 12 (mean $\pm$ SD) cm/sec, 10.4 ± 14.7 m, and $9.2 \pm 0.2^\circ\text{C}$, respectively. The fish showed sequential up-and-down movements near the thermocline during the twilight and during the daytime suggesting that the homing chum salmon allocated a proportion of their time to foraging. These data indicate that the homing chum salmon have navigation abilities in the homeward direction, and that salmon use ocean current transport to reduce energy expenditure during migration.

Lacustrine salmon populations offer an excellent model system for studying homing behaviors from open water to natal areas for reproduction. Homing migrations of mature lacustrine sockeye salmon, whose sensory cues were impaired by ablations, tracking from the center of the Lake Toya, a large caldera lake to their natal area using ultrasonic tracking system. Visual cues are critical to the straight homing of sockeye salmon, while magnetic cues do not appear to be necessary for successful return to the natal area (Ueda *et al.*, 1998). However, the Earth's magnetic forces during chum salmon homing migration in the Bering Sea was studied using magnetic tags that can record the magnetic force, and revealed that the homing migration route was approximately along the isoline of magnetic intensity (Azumaya *et al.*, 2016).

Spawning migration of lacustrine masu salmon attached with depth and temperature data loggers in Lake Toya clarifying that masu salmon can calculate the day length with an internal biological clock, because the diurnal movement after encounter with the river mouth might be usable to calculate the timing of upstream migration to their spawning river. To accurately home in open water, salmon must recognize exact locations (map) and compass direction (orientation) during migration, and must have an internal biological clock to calculate the duration from the feeding ground to the spawning ground (Ueda, 2016).

Neuroendocrinological Hormone Control Mechanisms of Imprinting and Homing Migration in Salmon

Salmon imprinting downstream migration in juveniles and homing upstream migration in adults are closely related to seawater adaptation and gonadal maturation, and are under the complex regulation of endocrine hormones mainly by the BPT axis and the BPG axis, respectively. The BPT axis involves thyrotropin-releasing hormone (TRH) in the brain, thyrotropin (TSH) in the pituitary gland, and thyroxine (T4) and triiodothyronine (T3) in the thyroid gland. The BPG axis involves salmon gonadotropin-releasing hormone (sGnRH) and chicken gonadotropin-releasing hormone-II (cGnRH-II) in the brain, luteinizing hormone (LH) and follicle-stimulating hormone (FSH) in the pituitary gland, and estradiol- 17β (E2), testosterone (T), 11-keto testosterone (11 KT), and $17\alpha,20\beta$ -dihydroxy-4-pregnen-3-one (DHP) in the ovary and testis.

It has been impossible to link hormonal control mechanisms to imprinting and homing migration of salmon because molecular markers that could permit the evaluation of memory formation and retrieval in the brain were lacking. Synaptic plasticity is thought to underlie the formation of memory. Long-term potentiation (LTP), which is a persistent strengthening of synaptic activity produced a long-lasting increase in signal transmission between two neurons, is widely considered one of the major cellular mechanisms that underlies memory formation and retrieval. The N-methyl-D-aspartate receptor (NMDAR) is a glutamate receptor channel subtype, mediates most of the fast-excitatory synaptic transmission in the central nervous system, and induces LTP. NMDARs are comprised of two subunits: the essential NR1 subunit and the differentially expressed NR2A-D subunit.

In the brain of hatchery-reared underyearling juvenile chum salmon, the gene expression of TRH increased immediately after release from a hatchery into the natal stream, and then the gene expression of NR1 increased during downstream migration. Gene expression of sGnRH and NR1 increased in the adult chum salmon brain during homing from the Bering Sea to the natal hatchery. Oral T4 administration in juvenile chum salmon enhanced NR1 gene activation. Juvenile imprinting downstream migration and adult homing upstream migration of chum salmon are controlled by endocrine hormones and could be clarified using NR1 as a molecular marker in the brain (Ueda *et al.*, 2016).

In Lake Shikotsu, a large caldera lake in Hokkaido, homing profiles of adult lacustrine sockeye salmon were different between males and females: 100% of males returned faster than females in early spawning season and 50% of males did not return to their natal spawning areas in late spawning season. In contrast, 70–90% of females returned over the spawning season. GnRH analog (GnRHa) treatment was highly efficient in shortening the homing duration of lacustrine sockeye salmon due to increases of serum DHP levels in both sexes (Sato *et al.*, 1997). Homing duration of male lacustrine sockeye salmon was significantly prolonged by NMDAR antagonists (APV and MK-801). These data suggest that GnRH and NMDAR are critically involved in salmon homing migration.

Neurobiological Olfactory Memory Formation and Retrieval of Natal Stream Odors in Salmon

Salmon olfactory organs respond only to limited dissolved chemical compounds, such as amino acids, steroids, bile acids, and prostaglandins. Electrophysiological responses of the olfactory nerve in masu salmon to artificial stream water (ASW) based on the composition of dissolved free amino acid (DFaa) were closely resembled to the corresponding natural stream water (Shoji *et al.*, 2000). DFaa concentration and composition of the Teshio River, Hokkaido, were analyzed during juvenile salmon downstream migration in spring and adult salmon upstream migration in autumn with a 4-year difference, and found that there were some

stable DFAA compositions between the spring and autumn samples within a 4-year span. Behavioral experiments of upstream selective movement in a 2-choice test tank (Y-maze) consisting of two water inlet arms and one pool revealed that four-year-old mature male chum salmon captured in the Teshio River showed significant preference for these stable DFAA compositions (Yamamoto *et al.*, 2013). The origin of DFAA in stream water was investigated focusing on biofilms that consists of various microorganisms embedding into a matrix of extracellular polymeric substances in the stream bed by incubation experiments in the laboratory. The DFAA concentration increased greatly in the biofilm incubation solution of the treatment group, but the DFAA composition showed little change after incubation, which was like stream water, suggesting that biofilms are a major source of DFAA in stream water. One-year-old sockeye salmon can imprint a single amino acid before and during smoltification, and that imprinting requires exposure for at least 14 days in the artificial rearing environment. These findings indicate that the long-term stability of the DFAA compositions in natal streams is crucial for olfactory imprinting and homing in Pacific salmon.

Behavior experiments were compared to test attractant effects on upstream selective movement among the four Pacific salmon species (pink, chum, sockeye, and masu salmon) using artificial natal stream water (ANW) prepared to the same composition and concentration of DFAA in their natural natal stream in the Y-maze. In both ANW and natural lake water, pink salmon showed the highest percentage of upstream movement among the four Pacific salmon species, but showed the least selectivity in the arm running ANW, whereas the other three Pacific salmon species (chum, sockeye, and masu salmon) showed significant selectivity in the arm running ANW. These results indicated that ANW had different attractive effects on upstream selective movement among four Pacific salmon. Pink salmon showed the highest upstream movement and the lowest selectivity to the artificial natal stream water (Ueda, 2016).

Impacts of Climate Changes on Migratory Fish

Climate changes concerning sea and lake levels, thermal structure, oceans currents, and acidification (seawater and freshwater) have caused many negative and a few positive impacts on important fisheries resources, habitats, and distributions of migratory fish. Migratory fish show different response to water temperature-dependent climate changes between cold-water species and warm-water species.

The stocks of Japanese chum salmon (a cold-water species) peaked in 1996 because of the successful improvement of propagation techniques and favorable habitats conditions in the North Pacific Ocean. However, numbers of adult return subsequently decreased rapidly, mainly due to high-water temperature along the coastal sea of northern Japan where adults make homing migration to their natal streams. In contrast, the stocks of Japanese amberjack or yellow tail (*Seriola quinqueradiata*: a warm-water species) increased steadily, mainly due to high-water temperature along their migratory routes in recent years. Their distribution areas move up to the north, and their catches increased in the northern Japan, especially in Hokkaido.

Physiological biotelemetry researches are valuable to reveal how migratory fish can navigate in open water using compass, map, and biological clock in response to new environments caused by climate changes. Molecular biological and biochemical endocrinological researches are necessary to reveal how and which endocrine systems involved in growth and reproductive migration of migratory fish respond to climate change-related new environments. Neurobiological researches are important to clarify which sensory systems involved in memory formation and retrieval of their spawning environments that might be affected by climate changes.

Migration and Navigation in Birds

Heather E Watts, Washington State University, Pullman, WA, United States

© 2018 Elsevier Inc. All rights reserved.

Introduction

Migration is the movement of an animal between distinct habitats or home ranges; these movements are greater in scale than those that occur as part of the regular daily routines of animals (Dingle and Drake, 2007). Most commonly, migratory movements, including those of birds, take animals between a breeding location and non-breeding location or wintering ground. Although migration is itself an energetically demanding process, it allows animals to make use of resources that vary in space and time, such as food sources that are only available seasonally. For example, Gambel's white crowned sparrows (*Zonotrichia leucophrys gambelii*) breed at high latitudes such as in Alaska and northern Canada, where they can feed on insects that become abundant in the spring and summer. However, these high-latitude breeding sites become inhospitable in the winter. Therefore, the birds migrate to lower latitudes in the western US and Mexico for overwintering, where seeds, grasses and fruits are available to eat. In this way, migration allows birds to utilize resources that are available in a given area for only a limited period of time.

Types of Migration

Patterns of migratory behavior vary widely among species. The most well-known migrants are those species that make very predictable migrations that occur at the same times each year and move birds between the same locations each year. This type of migration is often called obligate, calendar, or to-and-fro migration. Most often birds move to breeding grounds in the spring and then to wintering grounds in the fall. Some species make an additional movement to a third location, such as a molt migration to a location for molting (i.e., replacing of the feathers). American redstarts, (*Setophaga ruticilla*), black-headed buntings (*Emberiza melanocephala*), Gambel's white-crowned sparrows, Northern wheatears (*Oenanthe oenanthe*), and red knots (*Calidris canutus*) are just a few well-studied examples of obligate migrants.

However, not all birds move so predictably. Migrations that occur less predictably in space and/or time are called facultative migrations. One form of facultative migration is nomadic migration. Nomadic migrants typically move unpredictably between different locations each year, such that they rarely return to the same location. Nomadic migrations also tend to vary more in their timing from year to year, and nomadic migrants may forgo migration in some years. Banded stilts (*Cladorhynchus leucocephalus*), gray teals (*Anas gracilis*), pine siskins (*Spinus pinus*), red crossbills (*Loxia curvirostra*), and Tengmalm's owls (*Aegolius funereus*) are examples of nomadic migrants.

It is also important to recognize that many species of birds (or, in some cases only certain populations within a species) do not migrate; instead they remain in the same location year-round. Such birds are referred to as permanent residents. For such a strategy to be successful, resources, particularly food, must be sufficiently available in the same location year-round. House finches (*Haemorrhous mexicanus*), spotted antbirds (*Hylophylax naevioides*), and gray partridges (*Perdix perdix*) are all examples of species that are permanent residents in at least some parts of their range. Furthermore, some populations are composed of a mixture of birds that migrate and birds that remain resident. Such populations are said to be partially migratory. In some cases, individual birds within a partially migratory population remain either migrant or resident for their entire lives. This is the case for European blackcaps (*Sylvia atricapilla*) where being migratory or resident is an inherited trait. In other species, such as tropical kingbirds (*Tyrannus melancholicus*) and skylarks (*Alda arvensis*), individuals can switch between being migrant and resident across years, depending on their body condition, social status, or prevailing environmental conditions.

In addition to nomadic migration, another form of facultative migration is fugitive or escape migration. Fugitive migrations are movements away from unpredictable and severe disruptions in the local environment, such as a severe storm or drought. They allow birds to escape these inhospitable conditions and return when the disruption subsides. Fugitive migrations can occur in any bird, regardless of their typical migratory pattern. Thus, obligate, nomadic, and partial migrants, as well as permanent residents, can all make fugitive migrations if necessary.

The Migratory Phenotype

Migration involves profound changes to the morphology, physiology and behavior of a bird. Prior to migration birds undergo a period of preparation. This includes an increase in feeding (known as hyperphagia) and, in some species, a shift in diet such as an increase in fruit intake. These changes in feeding behavior in turn support fat deposition, which increases dramatically in many species (Fig. 1). Ultimately, these fat reserves provide the fuel for migration (McWilliams et al., 2004). Birds also increase muscle mass, particularly through hypertrophy, an increase in size, of the pectoralis muscles, which power the wing downstroke and are critical to sustained flight (Fig. 1). Birds may also undergo changes that facilitate oxygen transport during the intense exercise involved in migration, such as increasing the proportion of red blood cells in the blood. The intensity of these preparations (e.g., extent of fat deposition) can vary seasonally (fall vs. spring migration) and across species, and migratory preparations have been suggested to vary with factors such as the length of the migratory journey and expected conditions *en route*. Moreover, in some

Fig. 1 Photos illustrating physiological preparations for migration. Subcutaneous fat deposition is visible in the furcular and abdominal regions as yellow tissue. The bird on the right has more extensive fat depots compared to the bird on the left. As premigratory fattening progresses, fat depots will even surpass those seen in the bird on the right. An increase in the size of the pectoralis muscles (muscle hypertrophy) can also be seen; on the right the muscles are bulging above the keel, this is not the case for the smaller muscles on the left. Photos are taken from pine siskins (*Spinus pinus*). Photos by H.E. Watts.

species, energy reserves that are deposited prior to migration or during stopovers may also provide energy for breeding efforts after arrival.

The preparatory period is followed by the expression of the migratory state. The immediate decision to begin a migratory flight is influenced by weather conditions such as precipitation, cloud cover, temperature and wind conditions, with warm weather, clear skies without rain, and no winds or tail-winds being most conducive to migration (Richardson, 1990). Time of day also influences when birds migrate. Many species of birds migrate at night, including numerous species that are otherwise diurnal in their activity patterns. Flying at night, rather than during the day, may occur because atmospheric conditions at night are more favorable for flight and/or for preventing dehydration and overheating (Berthold, 1996). Nocturnal flight may also be necessitated by the need to feed during the day. Despite these potential advantages of nocturnal migration, there are other species that migrate during the day.

In some species, such as bar-tailed godwits (*Limosa lapponica baueri*), migration occurs primarily as a single non-stop bout of flight, whereas in other species migratory flight is interrupted by frequent periods of stopover, during which birds refuel before resuming flight. Stopovers typically last a few days to a couple of weeks, during which time birds forage in order to replenish fat depots and prepare for further migratory flight. In selecting stopover sites, birds must select locations with sufficient food availability for refueling. The length of stay at a stopover site is influenced by the bird's condition when they arrive, as well as their ability to refuel at the site.

Once birds have arrived at their destination, migration terminates. This process of arrival and settlement is perhaps the least understood step in migration. In many species, arrival in the general geographic area of the destination is followed by a period of local movement as birds locate suitable habitats or sites before settling. Upon arrival birds may also maintain a degree of readiness to resume or continue moving if conditions are unsuitable or deteriorate (Ramenofsky and Wingfield, 2006).

Navigation

For to-and-fro migrants, migration involves travelling between the same breeding and wintering grounds each year. How these birds find their way during migration has been a question of great interest to scientists. Although we do not yet have a complete picture of how this is accomplished, we do understand several mechanisms that birds use to navigate. Birds have at least three biological compasses that they can use to orient themselves in space. Birds are able to use (1) the sun and patterns of polarized light, (2) earth's magnetic field, and (3) stars to orient (Berthold, 2001). Moreover, evidence suggests birds may often use a combination of these cues. For example, thrushes belonging to the genus *Catharus* appear to use cues from the sun at twilight to determine a migratory direction and then use a magnetic compass to maintain that direction during their nighttime flight (Cochran et al., 2004). Each biological compass requires a sensory mechanism to detect the cue, which is then processed by the brain. Recent research has focused on understanding how birds detect and process magnetic information for orientation, and there is now evidence that both the eye and beak contain magnetoreceptors that could function in the magnetic compass (Mouritsen and Ritz, 2005). Although birds can determine direction using one or more of the biological compasses, a compass alone does not inform a bird

about its relative location on the landscape. Although a number of potential mechanisms have been proposed by which birds might determine their location, few are well supported by empirical evidence. The best evidence for such a mechanism one is based on spatial cues that birds learn *en route* and at destinations in order to aid in navigation during subsequent migrations (Mettkke-Hofmann and Gwinner, 2003). While such cues are useful for adults, young birds lack such cues on their first migration.

The first time a bird migrates from the breeding grounds where it was born to its wintering grounds, it must travel a route it has never taken to a destination it has never seen. To do this, birds make use of a genetically inherited migratory direction. This migratory direction sets birds off on a trajectory towards their destination and is coupled with a programed duration of migration. Together this use of direction and duration of migration, which is referred to as vector navigation or clock-and-compass orientation, leads juvenile birds to their wintering grounds (but see Thorup *et al.* (2010) for a discussion of the limitations of this explanation). In flocking species, juveniles may make use of the knowledge of experienced adults by following them. But even species that typically rely on experienced guides may also be able to vector navigate, presumably as a backup mechanism (Mouritsen, 2003). Once a bird has completed this initial journey, it has had the opportunity to gather information on the breeding and wintering grounds that it may use on subsequent migrations. A bird will also have been able to gather information *en route*. Therefore, it is possible that birds could make the return journey to the breeding grounds by retracing their outbound route. However, in many species, birds take a different migratory return route. Consequently, vector navigation is likely used in combination with information that was previously learned about habitat, latitude, or landmarks on the breeding grounds or *en route*. Once birds have completed the entire outbound and inbound migratory journey the use of learned spatial cues seems to take precedence in navigation, though birds continue to possess the ability to vector navigate (Mouritsen, 2003).

Timing of Migration and Connections to Reproduction

In many birds, reproduction and migration are tightly linked in the annual cycle (Fig. 2). Preparation for breeding often begins with migration to the breeding grounds, and the termination of breeding can be closely tied to the migratory departure to the wintering grounds. In order to prepare for breeding, most birds undergo seasonal development of the reproductive system, a process coordinated by activation of the hypothalamic-pituitary-gonadal (HPG) axis. The HPG secretes reproductive hormones leading to the development of a gonad capable of producing gametes. Although some species, typically those that move only short distances, do not undergo the process of gonadal development until after they arrive on the breeding grounds, many species undergo gonadal development during migration and arrive on the breeding grounds in a state of near-readiness to breed. In Gambel's white crowned sparrows, for example, initial activation of the HPG axis begins on the wintering grounds. By the time birds arrive on the breeding grounds, males are producing mature spermatozoa in the testes and females have enlarged ovarian follicles, though they have not yet begun yolk synthesis or deposition (Ramenofsky and Wingfield, 2006).

Appropriately timing events like migration and reproduction is critical to the survival and reproductive success of individual birds, and ultimately to the persistence of bird populations. If birds arrive on the breeding grounds too early, conditions may still be inhospitable and their survival may be threatened. On the other hand, birds that arrive too late may not have enough time to complete breeding, or they may miss peak food availability which could compromise their reproductive success. The question of how birds time their migrations has been best studied in obligate migrants. Therefore, that is the focus here, but for greater

Fig. 2 Example of an annual cycle typical of many temperate zone birds.

discussion of other migratory types see [Watts et al. \(In press\)](#). Among obligate migrants increasing day length (photoperiod) in conjunction with an endogenous circannual rhythm are important mechanisms initiating spring migration ([Gwinner, 1996](#)), while other environmental conditions, such as temperature, can fine-tune the timing. Increasing photoperiod stimulates activation of the HPG axis, which is also important in preparation for breeding, and leads to increasing levels of circulating androgens, notably testosterone. In both males and females, increasing androgen levels are important in stimulating the behavioral and physiological changes associated with the transition to spring migration ([Wingfield et al., 1990](#)). Activation of thyroid hormone signaling pathways in the brain in response to increasing photoperiod is also critical in the spring migratory transition ([Pérez et al., 2016](#)).

The mechanisms triggering fall migration are not as well studied as those operating in the spring. As for spring migration, photoperiod (experienced in the fall as well as those experienced earlier in the year) and endogenous circannual rhythms likely play important roles. On the other hand, the endocrine mechanisms underlying the transition to a migratory state appear to differ from those in spring migration, though they are currently not well understood. The timing of fall migration tends to be more variable than spring migration, which likely reflects sensitivity to local environmental conditions (e.g., temperature, food availability) and differences among individuals in their progression through breeding and the feather molt usually needed before the migratory flight. For example, when breeding of mountain white-crowned sparrows is delayed due to heavy snow cover, birds subsequently delay the fall migratory departure ([Morton and Pereyra, 1994](#)).

Just as circumstances around breeding events can influence fall migration, so too can spring migration influence breeding. In many species, it has been found that birds arriving earlier on the breeding grounds enjoy greater reproductive success than later arriving birds. For example, in American redstarts (*Setophaga ruticilla*), which migrate from wintering sites in the Caribbean and Central and South America to breeding sites in the United States and Canada, earlier arrival corresponds to greater reproductive success in males. The potential advantages of earlier arrival for redstarts and other species include access to more and/or higher quality territories and mates, as well as the potential to lay more clutches during the breeding season. Interestingly, studies across a variety of species have revealed that it is those birds in the best physical condition that arrive earliest. Among American redstarts, males that winter in better quality (in this case, wetter) habitats are in better physical condition at the end of the winter, depart for spring migration earlier, and arrive on the breeding grounds earlier than males that winter in poorer habitats ([Marra et al., 1998](#)). Given the correlation between migratory timing and physical condition, it is difficult to disentangle whether the superior reproductive success of early arriving birds is a result of their earlier arrival or their superior condition, or a combination of the two.

Impacts of Climate Change on Migration

Changes in the earth's climate over the past century, including warming trends, are having considerable impacts on patterns of bird migration ([Carey, 2009](#)). Perhaps the most widely documented change has been in the timing of spring migration. In many species, birds are arriving on their breeding grounds earlier in the year. This may occur as birds adjust the timing of migration in response to conditions, such as warmer temperatures or advancing plant phenology, on their wintering grounds or *en route* (e.g., at stopover sites), though changes in the location of wintering grounds (see below) could also contribute ([Knudsen et al., 2011](#)). However, not all species or populations are showing such shifts in spring migratory timing.

The consequences of climatic shifts depend on the details of how conditions such as food availability are changing relative to changes in the timing of spring migration. In many species it has been found that the timing of arrival on the breeding grounds is becoming increasingly mismatched to the timing of food availability in the spring, a critical resource for successful reproduction. In some cases, this is occurring as species fail to advance their spring arrival. Pied flycatchers (*Ficedula hypoleuca*) in the Netherlands, for example, have advanced their spring breeding to some extent, but they are limited by arrival time, which has not advanced ([Both and Visser, 2001](#)). In other cases, birds are advancing the timing of their spring arrival but not enough to keep up with even greater advances in the timing of spring food availability. And in yet another scenario, birds are advancing their spring arrival but conditions on the breeding grounds have not advanced. For example, American robins (*Turdus migratorius*) in the Rocky Mountains have advanced their arrival on their high-altitude breeding grounds, presumably in response to conditions at their lower-altitude winter grounds. But the timing of snowmelt on the breeding grounds, which determines spring food availability, has not changed; the result is that robins must wait longer for food to become available ([Inouye et al., 2000](#)).

The effects of climate change on the timing of fall migration are not as well studied, but the effects seem to be even more varied than those on spring migration. Some species or populations are departing the breeding grounds earlier, while others are departing later, and yet others show no change. In addition to effects on the timing of migration, climate change is also altering the distances that birds migrate. The most common effect is for migratory distances to be shortened. Birds belonging to a number of species that breed in Europe have been documented overwintering at higher latitudes, closer to their breeding range, in recent decades compared to in the past. Furthermore, some populations are becoming increasingly sedentary, with fewer birds migrating and more birds remaining resident year-round ([Newton, 2010](#)).

Summary

Birds express a range of migratory patterns, from highly predictable obligate migration, to less predictable nomadic and fugitive migrations. Typically, spring migration moves birds from their wintering grounds to their breeding grounds, and fall migration returns birds to their wintering grounds. Frequently, migration is preceded by a period of physiological preparation, which can

include increases in fat deposition as an energy reserve for migratory flight and increases in the size of the flight muscles. Once preparations are complete, the initiation of migratory flight is often influenced by weather conditions such as precipitation and wind. Many birds migrate at night, even species that are typically diurnal. As the migratory journey progresses, birds may make stopovers to refuel along the way. The process by which migration terminates once birds reach their destination is one of the least understood aspects of migration. In order to find their way on their migratory journey, birds may make use of several biological compasses, as well as inherited migratory programs, and learned landmarks on the landscape. Birds time their migrations using cues in the environment, most notably day length, and an endogenous circannual clock. Events during migration and breeding are often closely linked such that the timing or success of one stage is influenced by the other. Changes in the earth's climate over the past century are having impacts on migratory timing and migratory patterns, as well as the extent to which the timing of migration matches the availability of key resources.

Behaviour: Migration and Navigation (Sea Turtles)

Paolo Luschi, University of Pisa, Pisa, Italy

Introduction

The seven extant species of marine turtles have complex life cycles that encompass long periods spent on the move, during which turtles often perform extended movements spanning over hundreds of km and lasting months or even years. In many cases, these movements have a clear migratory nature and are directed to individually-specific target sites, which frequently are of limited extension. Migrating turtles will then have to rely on efficient navigation systems to guide their movements, either when moving along coasts or in shallow water or while swimming in the vastness of the ocean, especially when heading to remote islands. This is particularly the case of adult individuals which, at every reproductive season, leave their residential foraging grounds and migrate towards their breeding/nesting sites: since these two places are typically located in different, often distant, regions, males and females face the problem of finding their way to reach them. The present chapter specifically focuses on the reproductive movements of adult turtles, that are more clearly configured as true migrations directed towards specific areas and, as such, surely involve navigational aspects. It is worth to recall however that important findings have also been obtained on non-breeding juveniles and newborn hatchlings, that have provided most relevant information on the spatial ecology and orientation abilities of these life stages (reviewed in [Luschi et al., 2003](#)).

The orientation and navigation mechanisms allowing mature turtles to migrate towards their distant destinations have been the subject of many conjectures and hypotheses, that are however difficult to be tested experimentally mainly because of the large technical and logistical difficulties encountered when studying migrating turtles ([Lohmann et al., 2008](#)). In spite of their origin from terrestrial ancestors, sea turtles are indeed genuine marine animals spending most part of their life submerged in the water, often in remote or inaccessible areas, and as such are very difficult subjects for any experimentation. Only with the advent of efficient tagging and tracking techniques, and in particular of satellite telemetry ([Godley et al., 2008](#)), substantial advances have been possible. Sea turtle movements can now be reconstructed with fair accuracy anywhere in the world and this allowed to collect empirical evidence on the migratory behaviour and navigational skills of migrating turtles. Also, such reliable tracking techniques have allowed researchers to perform experiments aimed at testing specific hypotheses on turtle navigation, for instance by altering the sensory abilities of migrating turtles or subjecting them to translocation (homing) experiments. In this way it has been possible to outline the main characteristics of turtle migrations in a satisfactory way and to document the actual navigational performances during these journeys, so to propose firm hypotheses on the orientation/navigation systems they rely on.

General Phenology of Sea Turtle Reproductive Migrations

With the notable exception of flatback turtles (*Natator depressus*), the other six species of marine turtles are migratory to some extent. In some species/populations the adults' reproductive migrations are limited to short-range movements between the nesting beach and nearby foraging areas, but in most cases adults undertake long-range migratory travels, that can involve prolonged open-sea legs or even transoceanic crossings. Even if the main features of adult migrations are now quite well known, the available information is largely biased towards the case of postnesting migrations of females, that are the only class of individuals that are easily accessed and captured during the egg-laying process on a beach. Conversely, quite scant data are available for the reproductive migrations of males and on the pre-breeding movements of both males and females ([Godley et al., 2008](#)).

Satellite findings have allowed to distinguish two main types of migrations in turtle females ([Luschi et al., 2003](#)). In most Chelonian (hard-shelled) species, females leave the nesting beach to swim directly towards a fixed feeding area in the neritic environment, usually of limited extension, where they then remain for long time. At the following breeding season, 1–4 years later, they will migrate back from this residential/foraging site to their nesting area, therefore performing regular, shuttling migrations between two well-defined terminals. The best examples of this kind of migrations are found in green (*Chelonia mydas*) and loggerhead (*Caretta caretta*) turtles ([Fig. 1](#)), but similar patterns are also known in hawksbills (*Eretmochelys imbricata*) and Kemp's Ridleys (*Lepidochelys kempi*). During these migrations turtles may follow coastal routes when moving along continental edges, but they will also have to cross oceanic areas when nesting and/or foraging in or around islands ([Fig. 1](#)). Tagging and satellite tracking data have shown that, after every breeding season, each turtle returns to a specific, individual foraging site, often following similar routes in successive migrations ([Fig. 1\(b\)](#)). In contrast, pelagic-dwelling turtles, like the Olive Ridley (*Lepidochelys olivacea*) and, especially, the soft-shelled leatherback (*Dermochelys coriacea*), do not have spatially-limited foraging sites and mostly move over offshore areas while searching for their pelagic prey. Their postnesting migrations are therefore undirected towards a fixed site and their migratory courses appear more complex and convoluted than those of the other species ([Fig. 1](#)), and are better described as long-range wandering movements.

Variations to this general pattern do however exist, and the most recent findings have clearly revealed the presence of a large behavioral variability in turtle migratory behaviour. This is especially true for loggerhead turtles, that can present some variants to the usual migration pattern described above ([Godley et al., 2008](#)). Loggerheads living in temperate zone, for instance, may have

Fig. 1 Examples of postnesting migrations reconstructed by satellite tracking in (a) four green turtles nesting in peninsular Malaysia (data from Luschi, P., Papi, F., Liew, H.C., Chan, E.H., Bonadonna, F., 1996. Long-distance migration and homing after displacement in the green turtle (*Chelonia mydas*): A satellite tracking study. *Journal of Comparative Physiology* 178A, 447–452), (b) three loggerhead turtles nesting in Southern Italy (data from Mingozi, T., Mencacci, R., Cerritelli, G., Giunchi, D., Luschi, P., 2016. Living between widely separated areas: Long-term monitoring of Mediterranean loggerhead turtles sheds light on cryptic aspects of females spatial ecology. *Journal of Experimental Marine Biology and Ecology* 485, 8–17), (c) nine leatherback turtles nesting in KwaZulu-Natal, South Africa (data from Luschi, P., Lutjeharms, J.R.E., Lambardi, P., *et al.*, 2006. A review of migratory behaviour of sea turtles off southern Africa. *South African Journal of Science* 102, 51–58. Robinson, N.J., Morreale, S.J., Nel, R., Paladino, F.V., 2016. Coastal leatherback turtles reveal conservation hotspot. *Scientific Reports* 6, 37851). The yellow circle indicates nesting site location. In the first two cases, turtles migrated towards spatially-restricted neritic sites (identified by white squares), while leatherbacks moved over large oceanic areas. In panel (b), two successive migratory routes of the same female are shown, represented by orange and red, and by blue and green tracks.

more than one foraging site, and undertake seasonal migrations between distinct summer and winter areas at different latitudes. In other cases, postnesting loggerheads do not migrate to localized neritic sites, but rather frequent oceanic waters, where they display wandering movements similar to those of pelagic turtles. Interestingly, this alternative strategy likely involves a diet shift from benthic to epi-pelagic prey and is followed by only a part of the turtles nesting at a given site, with the remaining turtles following the usual pattern of migrating towards a neritic site. A similar dichotomy in migration strategy involving occupancy of oceanic waters have been also described in green turtles, an even more surprising finding since deep oceanic waters do not offer many foraging opportunities to these herbivorous turtles.

As mentioned above, similar detailed information is not available for males and for the pre-breeding migrations. Males spend virtually all their life in the water and so deployment of satellite tags is only possible upon their accidental or intentional capture.

Fig. 2 Reconstructed routes of three loggerhead females migrating from their individual foraging sites along the Tunisian shelf to their breeding/nesting area in southern Italy. While two turtles took a rather direct route to their destination, the third one (black line) nearly reached the Greek coast before heading to her breeding grounds. Data from Mingozi, T., Mencacci, R., Cerritelli, G., Giunchi, D., Luschi, P., 2016. Living between widely separated areas: Long-term monitoring of Mediterranean loggerhead turtles sheds light on cryptic aspects of females spatial ecology. *Journal of Experimental Marine Biology and Ecology* 485, 8–17.

Satellite tracking results have shown that males display a migration pattern similar to that of postnesting females, with the difference (however not extensively documented) that they migrate every year to reach the mating areas, that are typically close to the females' nesting beaches. The pre-breeding migrations of either males or females have been tracked in only a few cases, as a result of tagging at the foraging site or, more commonly, after a prolonged tracking covering the entire 2–3 year inter-reproductive period (examples in Fig. 2). The reconstructed routes are usually quite direct towards the breeding site, but although long detours have been recorded in some cases (Fig. 2), whose biological significance is uncertain.

Migratory Navigation: Biological Compasses

Students of animal navigation usually distinguish two distinct stages in the process of returning towards a previously known site (homing behaviour): first, the direction to keep to get back home has to be determined during the so-called 'map step'; then, during the subsequent 'compass step', the navigator has to keep and maintain that direction leading home, typically by means of a biological compass. The turtles' reliance on compasses is quite well ascertained, thanks to laboratory experiments in which turtle orientation is tested under controlled conditions. For instance, tests in water tanks have shown that newborn and juvenile sea turtles can refer to the sun's position (sun compass) or to stimuli deriving from the Earth's magnetic field (magnetic compass) to assume a given direction in space (Lohmann *et al.*, 2008).

Indications on the usage of a biological compass in natural conditions are more difficult to be obtained, again given the heavy logistical constraints when working with large wild animals. The open-sea courses reconstructed in tracked turtles are often remarkably straight, leading to the conclusion that they rely on a compass of some kind, possibly based on magnetic cues since straight movements persist during the nights, even when moonless. However, the simple presence of straight segments does not necessarily mean that turtles maintained constant headings, since currents usually contribute substantially to the observed movements of marine animals and the straightness of tracked routes can largely derive from current drift. Recent studies with loggerheads equipped with special data loggers recording headings have provided convincing evidence of a compass orientation in the open sea, probably through a magnetic compass (Narazaki *et al.*, 2009), but these findings are unfortunately so far limited to a few turtles only.

On the whole, the evidence provided by various laboratory experiments fits well with the findings of field studies in suggesting that turtles have one or more biological compasses in their orientation toolkit. It is likely that a sun compass is used during daytime when travelling at or close to the sea surface, while during nocturnal and/or deep-water movements, correct orientation may be assured by a magnetic compass.

Migratory Navigation: Navigational Mechanisms

Much more debated, and interesting, is the problem of how turtles animals navigate, i.e. how they establish their position with respect to a given site when away from it (the 'map step' described above). A number of navigational mechanisms have been described in different animals, but only some of them will be available to turtles, especially for movements taking place in the open sea. At least to an human eye, the open sea seems essentially featureless, lacking landscape features or other visual cues (generally indicated as landmarks) that are known to be of great help for terrestrial navigators: for instance we humans basically rely on such information to find our way in our normal life – at least when not guided by the GPS in our smartphone. Without the

help of landmarks, reaching a specific distant target at the end of an oceanic journey, under the effects of waves and currents, may indeed be a very hard task, as was well known to human seafarers before the advent of GPS and radio-controlled maritime navigation.

Even if landmark-based navigation seems prohibitive in the open sea, turtles can still refer to some kind of signposts ('sea-marks') that may be present, undetectable to humans, in the apparently uniform oceans. In seabirds, it is thought that olfactory cues, and in particular dimethyl sulphide, a volatile odorous substance produced by phytoplankton, may constitute an odorous landscape by which birds recognize previously visited open-sea locations and perhaps navigate over oceanic areas (Nevitt and Bonadonna, 2005). It is unknown whether turtles too may rely on such a mechanism, but it is remarkable that a sensitivity to airborne dimethyl sulphide has been demonstrated in loggerhead turtles (Endres and Lohmann, 2012).

Also, it is likely that turtles do use landmarks or other cues of terrestrial origin when moving along the coast or even when in shallow waters (e.g. visual features from the sea bottom). Satellite tracking data have shown how migrating turtles often tend to follow the coastline as long as possible, even when this results in long detours with respect to the straight line courses that would lead towards the final destination crossing the open sea (Fig. 3). Indeed, in many cases, the females' postnesting migrations are best described by a biphasal process, in which turtles first aim at crossing the open sea to reach a coast with the shortest and quickest route and then hug the coast until getting to their final destinations (Fig. 3; Hays *et al.*, 2002).

Fig. 3 Indirect courses taken by migrating turtles to reach a distant target. (a) Routes of two green turtles moving from their nesting site in Mexico (yellow dot) to their foraging sites (squares) in the Florida Keys. They followed a long, detoured route likely to remain in shallow/coastal waters and to avoid crossing the open sea. Data from Kinzel, M., 2001. Satellite tracking of green sea turtles in the Gulf of Mexico. *Argos Newsletter* 58, 5–7. (b) Routes of four green turtles migrating from breeding grounds at Ascension Island (yellow dot) towards their residential sites (squares) along the Brazilian coast. These turtles adopted a biphasal migratory strategy first covering the open sea stretch with the shortest route and moving along the coast until reaching to their destination. Data from Hays, G.C., Broderick, A.C., Godley, B.J., *et al.*, 2002. Biphasal long-distance migration in green turtles. *Animal Behaviour* 64, 895–898.

Fig. 4 Examples of migratory journeys directed towards an oceanic target: tracks of four green turtles that had nested on Chagos Islands in the Indian Ocean (yellow dot) and had their foraging sites (squares) in the shallow waters of the Amirante Banks, Seychelles Islands. Data from Hays, G.C., Mortimer, J.A., Ierodiaconou, D., Esteban, N. 2014. Use of long-distance migration patterns of an endangered species to inform conservation planning for the world's largest marine protected area. *Conservation Biology* 6, 1636–1644.

The situation is radically different for journeys taking place in the open sea, especially when directed to a specific target: how can a turtle find a small, remote island in the middle of the ocean after a trip of hundreds or thousands of km with no help of coastal/visual cues? The case is best epitomized by the green turtles nesting at Ascension Island, in the middle of the South Atlantic Ocean, that reach this tiny target migrating from the Brazilian coast, over 2000 km away. How can they do this is a unsolved question that is puzzling scientists from the time of Charles Darwin, who wondered about that when he visited the island on his voyage onboard the *Beagle*. Basically we do not yet have a clear answer to this question, and indeed we do not even know the modalities through which how ocean-moving turtles reach their specific targets, since not many females have so far been tracked while migrating towards foraging grounds located in oceanic islands (Fig. 4). Turtles have sometimes been found to arrive at their destination following curved, indirect paths or even after large detours (Hays *et al.*, 2014; Fig. 4).

Despite this paucity of empirical data, some hypotheses have been put forward to explain open-sea navigation in turtles, that however are corroborated by experimental indications in a few cases only. The most extreme hypothesis proposed is that turtles have no navigational information and move at random to find their target, more or less by chance. The directedness and efficiency of most turtle migratory journeys, makes this idea extremely unlikely, although the puzzling detours sometimes recorded (Figs. 2 and 4) as well as the responses of experimentally translocated turtles (see below) can be considered searching attempts for their targets. Such looping or convoluted routes could then be the result of a large-scale searching behaviour that may be not inefficient, since in most some cases turtles reach their destination after days or weeks of such convoluted journeys.

Another possible mechanism to explain oceanic navigation is the so-called vectorial navigation, by which an animal is informed about the distance and direction to travel to reach its target. For example, juvenile passerine birds are thought to possess an innate knowledge of the length and direction(s) of their migratory flight by which they guide their first journey towards their wintering sites: could an Ascension-bound turtle use a similar mechanism and find its target island by steering due East from Brazil and swimming for a certain amount of time? In theory, this is not impossible, but an Ascension-bound turtle only relying on such a simple information (that may be innate or acquired in some way), would then be totally dependent on possible inaccuracies in its steering mechanism and, especially, be exposed to passive translations due to the drifting effect of ocean currents (Lohmann, *et al.*, 2008). These factors cannot be corrected during movements taking place in the ocean, where the turtle orientation is not anchored in some way to stable cues like landmarks and where current drift play a major role. Detecting current drift while migrating would overcome this problem, as this would allow an immediate compensation for any shift from the due course, but such an apparently straightforward task is nearly impossible in the absence of stationary references and therefore is not a viable possibility for turtles travelling in the open sea - and for human seafarers as well. Recent studies have estimated the direction and speed of currents along the turtle routes and have showed that current drift effects on the oceanic movements are not negligible, and that turtles seem unable to detect the drift while swimming away from land (Galli *et al.*, 2012).

Reliance on vectorial information may still play a role in movements aiming at relatively large targets, like wide foraging areas or coastal sites, when any error can be corrected with the help of topographical features. For instance, in the biphasal postnesting migrations described before, turtles can correct navigational imprecisions during the oceanic leg of their migration after having reached the coast. Another way to correct for navigational errors may be to detect cues available in the relative vicinity of the goal, that may guide the final stages of target localization. Turtles translocated away from Ascension Island have been shown to return more easily when released downwind than upwind from the island, leading to hypothesize that the Southeast trade winds of the area may help turtles by generating a plume of wind-borne cues extending for tens of km in Northwest direction, which may act as

Fig. 5 Homing journeys of four turtles that had been translocated from their nesting site at Mayotte Is., in the Mozambique Channel (yellow dot), and released to open sea locations about 100 km away (green squares). Red and orange routes: turtles subjected to a magnetic treatment (application of a magnet to the head); blue and black route: control turtles. All turtles returned to the home island following indirect routes, but magnetically-treated individuals followed much longer, less efficient routes. As a result, the straightness of the homing paths resulted significantly lower in the magnetic group than in controls (insert). Data from Luschi, P., Benhamou, S., Girard, C., *et al.*, 2007. Marine turtles use geomagnetic cues during open-sea homing. *Current Biology* 17, 126–133.

an aerial beacon of airborne odors (Hays *et al.*, 2003). When inside such a plume, turtles would then be attracted by the island from some distance and could reach it simply by swimming against wind direction. Current-borne cues dissolved in the water can similarly exert such a beaconing effect, but no evidence for such a role has been ever been found in tracked turtles (Lohmann *et al.*, 2008).

The most efficient solution by which turtles could navigate is to rely on some kind of position-fixing mechanism through the development of large-scale maps. A turtle possessing such navigational maps would then be able to establish its position with respect to its target at any given location, irrespectively of whether it ended up in that position by its own motion and/or by the action of drifting factors - or because of experimental interventions. Reliance on such powerful mechanisms has been repeatedly proposed to explain the amazing performances of oceanic navigators, with several possible mechanism having been put forward (Lohmann *et al.*, 2008), but unfortunately the empirical evidence supporting them is limited. The most direct way to test reliance on position-fixing mechanisms is through displacement experiments, in which turtles are translocated away from a location where they reside (typically a nesting beach) and are then tracked to assess their ability to get back to the original home site. Performing such experiments is not an easy task, due to the enormous logistical problems involved in transporting nesting turtles tens of km away, but a few experiments of this kind have been made, also from oceanic islands, showing that displaced turtles are able to return home, although often by following circuitous routes (Fig. 5).

The sensory cues could be involved in such navigational maps have also been investigated. The best candidates for wide-ranging maps are geomagnetic cues, that are accessible everywhere and anytime and should indeed allow to establish one's position anywhere on Earth, although without high precision. A series of arena experiments with newborn loggerheads have shown that they can distinguish slightly different values of magnetic parameters (Lohmann *et al.*, 2008), and it is likely that this fine magnetic sensitivity is retained by juvenile and adult stages, that may develop a sort of geomagnetic map for large-scale navigation. In a milestone experiment, juvenile green turtles were tested in specially designed arenas while being exposed to magnetic fields matching those of locations about 300 km away from the test site, thus simulating a 'magnetic displacement' to these sites (Lohmann *et al.*, 2004). Tested turtles were faithful to the specific foraging areas where they had been captured and so the expectation was that they would orient towards home in the arena, just like they had been actually translocated to such locations. The turtle response was in accordance with this expectation, and the interpretation of these findings is unequivocal: tested turtles used geomagnetic cues to determine their (virtual) position with respect to home, and then oriented in such a way to correct the 'virtual magnetic displacement' they had been subjected to. This result, which unfortunately has never been replicated, provides the most clear-cut evidence so far available that the turtles can rely on large-scale magnetic maps to navigate.

The role of geomagnetic cues in oceanic navigation has also been investigated in natural conditions through different kinds of satellite tracking experiments. Green turtles migrating from Ascension Island to Brazil while being exposed to an artificial magnetic field created by mobile magnets around their body, were not affected by the treatment, showing that geomagnetic cues were not necessary at least to accomplish the migration towards continental Brazil (Papi *et al.*, 2000). In contrast, displacement experiments have highlighted the role of geomagnetic cues in green turtle navigation towards islands. In two successive experiments in the Indian Ocean (Luschi *et al.*, 2007; Benhamou *et al.*, 2011), turtles displaced to open-sea release sites were affected in their homing performances by the application of a mobile magnet glued to their head, being able to return to the home island only following longer and/or more or convoluted routes than controls (Fig. 5). These findings highlighted the role of geomagnetic information in

the homing process of freely-moving turtles, although it is not yet known whether the treatment specifically affected the turtles' magnetic map or another magnetically-mediated orientation process.

General Remarks

Satellite telemetry has provided a wealth of information on the migrations of adult marine turtles, by which various important aspects of the migratory behaviour of the different species have been documented, such as the kind and extent of the movements performed, the areas frequented during and after migrations, the behaviour during the journeys. Also, the reconstructed migratory courses revealed relevant navigational performances in ocean-moving turtles, that have often been found able to pinpoint a remote target following fairly efficient and accurate routes, even if not in all cases (examples in [Figs. 2–4](#)).

This relatively well-defined picture of migration phenology is not mirrored by our knowledge on the navigational aspects of the phenomenon: we still do not know how turtles find their way while migrating, and especially how they navigate to reach their final targets. On the whole, the best available results indicate that turtles may rely on a compass sense coupled with some kind of position-fixing mechanisms, possibly based on magnetic cues, to find their way during migrations. This would allow them to pinpoint their targets, even when distant and remote, overcoming the drifting effect of ocean currents. The recorded ability of turtles to compensate for actual or virtual displacements (although with some difficulties in freely-moving turtles), constitutes the best piece of evidence available for this idea, but these conclusions still derive from a few, sparse experiments, basically done on a single species, the green turtle, and with different experimental techniques. More empirical findings supporting this view should be collected before reaching a definitive conclusion. In any case, it is reasonable that migrating turtles would have other navigational options at their disposal when performing their long-distance migrations. Among these, reliance on short-range cues like wind-borne information or coastal topographical features available close to the targets, may facilitate the final stages of navigational processes.

It is therefore likely that the turtles' navigation system is actually composed by different mechanisms, active at different spatial scales, that act concurrently or sequentially during goal-directed navigation ([Bingman and Cheng, 2005](#)). Under this scenario, migrating turtles may rely on large-scale maps to get general positional indications, perhaps with a rather coarse accuracy, by which to determine the course towards destination and correct it during the journey. They could then integrate this information with other, more precise but not universally available, navigational cues to pinpoint the final target. We can try to 'translate' this hypothesis in practice by applying it to the concrete case of a turtle migrating in the ocean to return to its nesting beach after some years spent at its foraging sites. This could be a green or a loggerhead turtle moving from its coastal foraging area or a leatherback that has been wandering in pelagic waters for years before returning to its nesting beach. Initially, the turtle would determine the general migratory direction to keep by relying on its large-scale map (even if coarse in accuracy), and then start migrating maintaining this deduced heading with the help of its compass(es). During the oceanic leg, it may take advantage of map-like information even only intermittently, to avoid being displaced off route by current drift. This strategy should lead the turtle to arrive not far away from destination, where short-range mechanisms like those mediated by landmarks (for coastal sites) or wind-borne cues (for oceanic targets), may then enter into action and guide its final approach to the target. It is presently hard to tell whether this picture, still very speculative, is the correct one to explain sea turtle migratory navigation, and it can only be hoped that new empirical data will be collected in the near future to substantiate, or dismiss, this proposed view.

Introduction

For all organisms, reproduction is the key to success. In birds, reproduction is a multi-stage process that is only part way through when a bird finds a partner and mates. The next stages are the choice of location for laying eggs, which may or may not be followed by building a nest, and then the laying of eggs. Eggs are incubated, chicks hatch and are fed, in or out of the nest, by parents, siblings or sometimes, unrelated individuals or may simply be guided to appropriate foraging locations. Although it is only the female that can lay the eggs, there may or may not be division of labour between the parents at all of the other stages. Here we will provide an overview of the progression from nest site location to successful fledging of the chicks with a flavour of the diversity that occurs across species at each stage.

Nest-Site Location to Nest Building

For some birds, choice of location is all-important because they lay their eggs on the ground. Because the Common Ringed Plover *Charadrius hiaticula*, for example, lays its eggs on dry riverbeds, the colour patterning of its eggs must be camouflaged against the background. Nesting female plovers may also attempt to redirect potential predators away from their nest by pretending to be injured, dragging a wing along the ground as they move away from the nest. Razorbills *Alca torda* and Common murre *Uria aalge*, also simply lay their eggs on the ground but because they choose locations on cliff ledges, their eggs and chicks are already less accessible to most predators.

Most birds, however, build some kind of nest to hold their eggs and chicks, to protect them from weather and predators while creating a suitable microclimate for development. Nest building can loosely be defined as the ability to organise bits of material into a certain spatial relationship. This is a loose definition because 'organising bits of material' ranges from excavation of burrows (e.g. burrowing owls *Athene cunicularia*), to scraping material into a pile (e.g. Australian brush turkeys *Alectura lathami*), from piling sticks up into a platform (e.g. storks *Ciconia* spp., bald eagles *Haliaeetus leucocephalus* and other raptors) to weaving (e.g. weaverbirds *Ploceus* spp.). While nests are predominately used to hold eggs and young, adults may also build nests for roosting in over night (as do chimpanzees, which build a new nest each night). And, although birds are the group of animals most commonly associated with nest building, it is taxonomically widespread and observed in insects, spiders, fish, and mammals (Collias and Collias, 1984; Hansell, 2000).

Mate Selection

For some birds, nest building occurs earlier in the reproductive cycle and plays an integral role in courtship behaviour. Courtship is the act of displaying to a potential mate, often of either one or more physical characteristics, such as the number of eye spots in a peacock train or the rate of singing by male great tits or by engaging in a particular behaviour, such as nest building (Davies *et al.*, 2012). Courtship displays allow a potential mate, usually the female, to assess an individual's potential quality, either as a genetic parent or for their ability to perform upcoming parental duties. Although uncommon, for some species, the male builds more than one nest and females appear to choose among them. In wrens *Troglodytes troglodytes*, the male then completes that nest and the female lays her eggs in it while Cape weaver *Ploceus capensis* males appear to complete several nests before a female chooses one in which to lay her eggs. In these species it is not clear what features the female uses to choose a nest but penduline tit *Remiz pendulinus* females select males that have constructed larger nests. This is perhaps because eggs that are laid in larger nests are better insulated from the environment, which should increase the probability that those eggs survive to become chicks. In Australian reed warblers the value of the nest is clearer. Males build two types of nests in their territory; type 1 is structurally capable of holding eggs and young, and type 2, which is used for display. The more type 2 nests a male builds the more food there is available on the male's territory so making it easier for the female to provision her young. In other species, the building itself seems to be a useful measure of future parental care. For example, male magpies *Pica pica* that bring more sticks to a nest also later bring more food to their young. Female magpies can then use building as a cue for male future investment.

Nest Site Selection

Most of the time birds choose the location in which to build their nest once they have a mate. Sometimes the male chooses, sometimes the female and sometimes both together. There are eight broad categories of nest site: (1) ground nests, where nest contents are either on a small cushion of nest material, usually vegetation or stones, or directly in contact with the ground;

(2) nests floating on the water; (3) ground hole/cavity nests those that are either excavated by one or both adults or are built in holes excavated by other species; (4) grass/reed nests are supported by vertical stems; (5) nests that are built on branches in trees or bushes at any height above the ground; (6) cavity nests are built in openings in branches and trunks, either naturally or caused by previous excavators; (7) nests that are attached to cliffs and buildings walls; and 8) nests that are built on ledges, which are similar to wall nests, but have support from below (Mainwaring *et al.*, 2014).

The category of nest a bird builds is usually species specific. For example, cliff swallows *Petrochelidon pyrrhonota* always build nests on walls, while blue tits always build in a cavity off the ground, usually in a tree hole, but they will also use nest boxes, which has made them readily accessible for research on avian reproduction. Nest site location is influenced by a combination of factors: (1) risk and experience of predation; (2) presence or absence of conspecifics and non-threatening species, their breeding success and territory competition; (3) local climatic conditions and (4) availability of suitable nest material. For example, orange-crowned warblers *Vermivora celata* will shift from building in trees or shrubs to building closer to the ground if there are any signs of predators in the area. Alternatively, by building under hawk nests, black-chinned hummingbirds *Archilochus alexandri* use predator proximity to protect their chicks from jays (hawks prey on jays).

Previous experience of predation will cause Pinjon jays *Gymnorhinus cyanocephalus* to change their choice of nest site. They usually build their nests on the outskirts of trees or shrubs, possibly to take advantage of the solar radiation. If the eggs, or chicks, are taken by a predator, the following year, the unlucky would-be parents will build their nest closer to the trunk of the tree and to the ground. The nest is then better protected from predators, but is also more shaded from the sun.

Choosing a location for a nest can also be dependent on conspecifics. Nearly all seabird species, for example, nest in colonies. There are a range of costs to group nesting such as increased competition for nest sites, nest materials and food. But colonies also enable earlier detection of predators and increased protection through mobbing. Some birds e.g. sociable weavers *Philetairus socius* build a permanent, communal nest. The majority of birds, however, nest alone. By doing so the nest is less conspicuous to predators.

As one of the main purposes of a nest is to create a suitable microclimate for development, nest site selection can also be influenced by the ambient climate. Optimal temperature for offspring development is usually higher than the ambient temperature, and nests in northern temperate regions are often built in sites that lose less heat than do sites selected at random. Horned larks *Eremophila alpestris* building in cool parts of North America build a nest with an entrance that protects the nest contents from prevailing winds while in warmer locations, the nest is built so that its contents are shaded for most of the day, protecting the young from overheating by solar radiation.

Nest site selection can also be influenced by the availability of nest material. Typically, birds will use local materials but nest material specialists can be influenced by the availability of appropriate material. For example, song thrushes *Turdus philomelos* build a nest of mud and rotten wood, which they can struggle to find in dry and/or urban environments, so do not often build a nest in these areas.

Nest Construction

Once a site has been selected, the building begins. Builder may be the male, the female or both. Nest structure is often very similar within species but varies a lot across species, ranging from woven nests with a roof, through cup shaped to platform or little more than a scrape on the ground (Breen *et al.*, 2016).

The materials used for building are also highly variable, both within and between species. Typically, it is plant material or sometimes mud (swallows) or stones (penguins) but there are increasing examples of birds using human materials (e.g. crows in Tokyo build nests with coat hangers and ospreys in Montana using brightly coloured plastic agricultural twine).

How builders use material may depend on local climatic conditions. Populations in colder areas put more feathers, animal and/or other insulatory materials into their nests than do populations in warmer areas. For example, northern populations of European blackbirds *Turdus merula* build bigger nests than do southern populations, the further north that European blue tits build, the more feathers they include while the Hawai'i 'amakihi *Chlorodrepanis virens* adds more lining and builds denser nest walls the higher the altitude. Bigger nests and nests with more insulatory material, are slower to cool, which is advantageous in colder environments. By cooling more slowly, egg temperature does not decline to dangerous temperatures when the parents leave the nest, and the parents do not have to exert as much energy to rewarm the nest contents on their return.

The actual availability of nest material can also affect what goes into a nest. As most birds use what is available to them, the surrounding flora and fauna can influence the nest composition dramatically. Dartford warblers *Sylvia undata* building in Suffolk, for example, typically use small heather and moss while warblers building in Hampshire will construct a nest from grass. The differences in materials would lead birders from either region to mis-identify the builder.

Some birds, like starlings, may include fresh green plant material containing hydrocarbons, apparently as a defence against pathogens and parasites. House sparrows *Passer domesticus* and house finches *Carpodacus mexicanus* in Mexico City, perhaps lacking access to appropriate plant material, use cigarette butts as a measure to repel parasites: the more cigarette butts, the fewer parasites in the nest. Material may also be used to reduce the risk of predation, the most obvious example being the use of material to camouflage the nest. There is, perhaps, surprisingly, little evidence that birds in the wild actually do this although zebra finches *Taeniopygia guttata* building nests in the laboratory will choose material of the colour that matches the nest surroundings.

Egg Laying

With the nest complete (if there is a nest), egg laying can begin. Egg laying can take anywhere between 1–12+ days, depending on the species and the number of eggs produced (clutch size). Eggs are usually laid at a rate of one per day, but this can vary with species. Some birds will begin to incubate as soon as they have laid the first egg, for example barn owls *Tyto alba*, but most species will wait until all, or nearly all, of the clutch has been laid. By waiting until all of the eggs have been laid before incubating, the parents can more readily synchronise the time at which the chicks hatch (Deeming and Reynolds, 2015).

The egg-laying period can be quite a dangerous time for the parents. When the parent is not on the nest, eggs are entirely defenceless. Nesting in colonies is one way to protect eggs and chicks from predation. For birds that build nests in the open, natural selection has driven many to camouflage their eggs. Egg colouration might match either the nest or the substrate surrounding the nest and ground-nesting birds typically have particularly well-camouflaged eggs.

Brood parasitism is also a risk for some species. A brood parasite manipulates its host (either a conspecific or, more often, a different species) to incubate and raise its young. A female brood parasite e.g. the European cuckoo *Cuculus canorus* or the brown-headed cowbird *Molothrus ater* will lay eggs in multiple host nests. Most brood parasites are specialists, parasitizing only one host, although both the European cuckoo and the brown-headed cowbird are able to parasitize a wide range of hosts (e.g. cuckoo hosts: dunnoek *Prunella modularis* and reed warbler *Acrocephalus scirpaceus*; cowbird hosts: Eastern phoebe *Sayornis phoebe* and American redstart *Setophaga ruticilla*). The choice of which species to parasitize is passed down the maternal line. Brood parasites have evolved a number of ways to avoid identification and/or eviction by hosts. For example, if the host builds an open-cup nest, the brood parasite egg is usually remarkably similar in coloration to that of the host eggs. The parasitic young also hatch earlier and develop more quickly than do the host chicks. Furthermore, once hatched, the parasite chick will often evict remaining host eggs and/or the chicks from the nest. If the host nestlings are not evicted they usually starve, as the larger parasite outcompetes them for food.

Incubation

Incubation is an aspect of parental care peculiar to birds whereby the parent sits on the eggs and nestlings to keep them at a temperature that is optimal for development. By providing the appropriate temperature for an appropriate duration, Incubation enables the cluster of cells on an egg yolk surface to differentiate and develop into a hatchling. The remaining yolk is used as a nutrient reserve by the developing chick.

Incubation usually occurs by either one or both of the parents warming the eggs via a brood patch. A brood patch is a highly vascularised area on a bird's breast, where all the feathers have either been removed or fallen out. The brood patch then warms the eggs by conduction. During incubation the eggs are turned and moved by the parent(s) to ensure heat is transferred equally through the yolk. Turning the egg also prevents the egg membrane from sticking to the shell.

Not all birds use their body to incubate. Megapodes (also known as incubator birds) like the Australian brushturkey *Alectura lathamii* scrape together mounds of combustible vegetation and one or more females lay eggs in the centre. The brushturkey male then attends to the mound as it composts, regulating the internal temperature to around 33–35°C by adding and/or removing vegetation. Variation in the temperature in the mound leads to skews in the sex ratio of the offspring produced: cooler temperatures lead to the production of more sons and warmer temperatures results in more daughters.

But the majority of birds use their bodies to regulate incubation temperature. While in cooler climes, the aim of incubation is typically to keep the eggs and chicks warm, in locations where the ambient temperature is greater than the optimal temperature, or when the eggs are not shaded from the sun, the parent(s) may use their bodies to cool the eggs. By positioning themselves over the nest contents, they can shade the eggs and limit heat transfer, or alternatively soak their breast feathers and drop water onto the eggs to aid cooling.

The task of incubation can fall to just the female, just the male or both parents. In about 50% of species both parents incubate, in some shape or form, but the female often does the brunt of the work. The male is not usually idle: he may defend the nest, eggs, his territory and his female(s). In some species, he will provision the female while she remains on the eggs. Indeed, in hornbills (Bucerotidae), the female is entirely dependent on her mate because she nests in a tree cavity, the entrance to which she begins to fill in. Once she has laid her eggs and begins to incubate, her mate will all but seal the entrance with mud leaving just a small hole through which he can feed her. The female remains on the nest until the eggs have hatched, when she breaks free, reseals the nest and assists the male with provisioning the young. In some species, such as rufous hummingbirds *Selasphorus rufus* however, the female incubates alone without help from her mate. He continues to display throughout the whole of nest building, egg laying and post-hatch care of the young.

As with other parts of reproduction, the length of incubation is species specific. It can take anywhere from 11 days (small songbirds) to 85 days (wandering albatross *Diomedea exulans*). But the actual length of incubation can be affected by a variety of factors. For example, the amount of time a parent incubates is often flexible and often changes in response to environmental conditions. During wet and/or cold periods the parent(s) will remain on the nest for longer and take fewer and shorter bouts off the nest. By remaining on the nest the incubating parent can maintain the eggs at an optimal temperature, and also protect them from the rain. Also by reducing their bouts off the nest the parents themselves will not return to the nest sodden and drench the eggs, which could be detrimental. In contrast, during periods of dry and/or warm weather the parent(s) may be away from the nest for

longer periods, using the time to find food. Unless, that is, the ambient temperature exceeds that of optimal incubation temperature. During these times the parent(s) remain on the eggs for longer, to protect them from the heat and control the nest temperature.

The risk of predation can also affect parental incubation behaviour. In areas of high predation risk, parents take fewer and longer bouts off the nest. This reduces the chance that the parents advertise the nest location to potential predators. The availability of food may also affect incubation behaviour. In experiments where incubating adults have been supplemented with food, the parents spend less time searching for food and more time incubating their eggs/chicks. Such supplementary food can even decrease the incubation period by a few days. By the same token, a limitation in food supply can lead to an increase the period of incubation.

Furthermore, the health and age of the parents can influence incubation. Healthier birds spend more of their time incubating, possibly because they do not have to spend as much time searching for food, which reduces the incubation period. In some species, for example the southern fulmar *Fulmaris glacialisoides*, older birds are better incubators (success almost doubles as birds age from around 7 years old to around 19 years old), which again can reduce the incubation period.

Parental Care

Parental care is the investment provided by the parent(s) to ensure development and survival of their offspring. It can include providing food, providing protection and/or thermoregulating the young. The degree to which chicks are developed when they hatch affects the kind of care their parents typically provide (Cockburn, 2006).

Altricial chicks, which include the young of songbirds, at hatch are blind, featherless and completely dependent on their parent(s). The parent(s) will either bring the chicks pieces of food, or regurgitate food into their offspring's mouth and continue to do so until the chicks fledge which could take several weeks, depending on body size. The chicks encourage the parent(s) to provision them with food by engaging in begging. During early development the parent(s) must also continue to incubate the chicks as they cannot thermoregulate. Parental time is divided between feeding, incubation and their own upkeep.

The offspring of some species are considered to be semialtricial, for example, owls (Strigiformes) and hawks (Accipitridae). The new hatchlings of these species are immobile, unable to thermoregulate and are completely dependent on their parents for food but their eyes are open when they hatch.

The next level of dependency is termed semiprecocial, which describes the state of development of gull and tern chicks when they hatch. Semiprecocial chicks are feathered and mobile just after hatching but remain in or close to the nest. The chicks are dependent on the parent(s) for feeding and protection.

Chicks that leave the nest just after hatching and remain with their parent(s) are considered to be subprecocial. Just after hatching, the chicks, for example grebes (Podicipediformes), are either fed away from the nest or shown by the parent(s) where food can be found and what can be consumed.

The most developed at hatch are the young of precocial species, which include the waterfowl e.g. ducks, geese and swans. Precocial chicks leave the nest very soon after hatching and follow their parent(s). The chicks are able to feed themselves almost immediately, but do rely on their parent(s) for protection.

All chicks are, dependent on some form of parental care, at least early after hatching. And most avian parents engage in parental care, but there are two exceptions. Brood parasites do not care for their young as they give that responsibility to their hosts. But their chicks do still require parental care, albeit from unrelated, unwitting foster parents. The chicks of megapodes, however, are completely independent from hatching and are not reliant on their parent(s).

In some instances, care of the young is not just carried out by the parents, but by family members. This is known as cooperative breeding. The common explanation for the existence of cooperative breeding is that it occurs due to environmental constraints, such as limited territory or food availability. When territory is limited, helpers are waiting for a territory to become vacant but when food is limited, parents may not be capable of finding enough food for their chicks without the help of others.

Glossary

Agnatha A superclass of 125 extant species representing jawless fishes, and includes hagfish and lampreys – the majority of the representatives of this group are extinct. Jawlessness, considered a primitive trait, is not found in any other vertebrate group.

Anisogamy A form of reproduction in which dissimilar gametes fuse during fertilization. Anisogamous gametes (typically large, energy-rich eggs and small, motile sperm) have been invoked as a driving force behind sexual selection.

Chondrichthyes A superclass of more than 1200 species representing the cartilaginous fishes and including sharks, rays, skates, and chimeras. Unlike the bony fishes (Osteichthyes), the chondrichthyan skeleton is made of cartilage. All members of this group have internal fertilization.

Fertilization The process by which a female egg and a male sperm fuse to form the first cell of a new offspring. It may be internal, in which the union of gametes occurs within a specialized reproductive organ, or external, in which parents release their gametes into the external environment, where fusion takes place.

Group spawning A form of mating in aquatic animals in which multiple males and females simultaneously release their gametes into the external environment.

Mating systems Describe the number of mates per individual. A mating system may entail pair bonding between a single male and female (monogamy), a single male and multiple females (polygyny), a single female and multiple males (polyandry), or multiple males and females (polygynandry). Promiscuity refers to a mating system in which no social bonding occurs, and males and females may mate with any number of partners.

Osteichthyes A taxonomic megaclass including close to 32,000 species representing the bony fishes, including the ray-finned Actinopterygii and the lobe-finned Sarcopterygii. Osteichthyans can be identified by their bony endoskeleton, plate-like scales, and air-filled swim bladder.

Pair spawning A form of mating in which a single male and female release their gametes into the water for fertilization.

Parental care Behavior by either parent that increases offspring survival after fertilization. Care includes internal gestation, egg burying, mouthbrooding, nest guarding and feeding.

Parental investment Parental energetic and time contributions toward both pre-fertilization gametes and post-fertilization offspring.

Phylogeny Traces the evolutionary history of organisms and the evolutionary relationships between groups.

Territoriality A behavior in which an individual occupies and defends a specific area. Territorial animals may defend breeding sites or access to resources such as food or mates.

Introduction

Fish are the most diverse group of vertebrates, and include more than 33,000 species exhibiting a remarkable diversity of parental care behaviors (Froese and Pauly, 2017). While exclusive paternal care is rare in birds and absent in mammals, more than a quarter of fish families exhibit male-only care (Fig. 1), a factor that has made this group a central model in the study of the ecology and evolution of parental care. For the purposes of this article, parental care is considered to be any parental behavior toward offspring that enhances offspring survival. While parental investment in gametes is thought to be a primary determinant of offspring success, parental care behaviors after mating are often essential for offspring growth and survival (Blumer, 1982).

Trends in Parental Care in Fish

Ecological Overview of Care

Over 95% of caregiving fish species are guarders, where one or both parents defend the nesting site (Gross and Sargent, 1985). Other common forms of care include nest maintenance during offspring development, substrate cleaning, in which the site of egg deposition is cleaned, and fanning, in which the parent waves its fins over developing offspring to provide aeration or to remove sediment. A number of groups of fishes employ mouthbrooding, in which one or both parents carry developing offspring in their oral cavity. While the male is the sole provider in the majority of fish species in which care has been documented (Fig. 1), internal gestation (retention of fertilized eggs within a brooding organ) is typically carried out by the female, with the notable exception of the male-pregnant syngnathids (seahorses, pipefish, and seadragons (Stolting and Wilson, 2007)). In most cases, parents care for fertilized eggs before hatching; less than six percent of care extends to fry and juveniles (Gross and Sargent, 1985).

Fig. 1 Phylogenetic distribution of parental care in vertebrates. Phylogenetic tree showing genetic relationships among major vertebrate groups (After Amemiya, C.T., Alföldi, J., Lee, A.P., *et al.*, 2013. The African coelacanth genome provides insights into tetrapod evolution. *Nature* 496(7445), 311–316) and relative representation of care behaviors in each group, based on the dominant mode of care shown at the family level. *Note: Alternative forms of avian care (brood parasitism, cooperative breeding) *sensu* Cockburn (2006) not shown.

Interestingly, there is a major difference in the frequency of parental care in marine and freshwater environments, and while less than 20% of marine fish display care, parental care is found in more than 50% of freshwater species (Gross and Sargent, 1985). The widespread pelagic egg stage has been suggested to obviate the need for care in marine fishes, as the open sea is a more uniform environment with fewer egg predators and a higher egg survival rate relative to freshwater (Clutton-Brock, 1991). Guarding and nest building are thought to be more beneficial in freshwater environments, as favorable spawning sites are less abundant and unevenly distributed (Clutton-Brock, 1991). Care is especially uncommon in fish greater than 10 cm in length, possibly because larger fish tend to produce large numbers of pelagic eggs, whereas smaller fish produce fewer eggs that can be protected by small caves and cavities in the local environment (Clutton-Brock, 1991).

Phylogenetic Overview of Care

The role of evolutionary history is an important component in the study of any aspect of life history, including parental care, and incorporating phylogenetic relationships can help to clarify the major trends and drivers of caring behavior. Given their great diversity of care forms, bony fishes represent an ideal model in which to test evolutionary models of parental care. The last comprehensive review of parental care in fish was carried out by Blumer in 1982, and while subsequent studies have investigated evolutionary correlates of care in particular groups (e.g., Goodwin *et al.*, 1998; Ah-King *et al.*, 2005; Mank *et al.*, 2005; Kolm *et al.*, 2006), there has been no systematic attempt to update Blumer's analysis, despite the steady accumulation of studies detailing care behaviors in a wide variety of fish species. At the same time, the phylogeny of fish is better resolved than at any time in the past (e.g., Betancur-R *et al.*, 2013), due to the availability of genetic and genomic data for many species.

Here, we present the results of a systematic and comprehensive review of parental care in fish. Relying heavily on the public collection of life history data in FishBase (Froese and Pauly, 2017), we present data for 294 of 514 bony fish families (Fig. 2). While our updated review includes close to 60% of fish families, an examination of the data reveals the overrepresentation of

reproductively unique and commercially important groups (e.g., all but 3 of the 298 species of male-pregnant Syngnathidae have been investigated, and Cyprinidae, which includes highly-fished species such as carp, represent a large portion of parental care studies), and highlights the fact that unstudied groups may show cryptic diversity in care behaviors. For instance, recent work on Antarctic icefishes (Family Harpagiferidae) has revealed a wide range of parental behaviors in this group, including male, female, and biparental care (Detrich *et al.*, 2005), underscoring the need for continued research into the basic life history of many groups. Given the high taxonomic diversity of fish, we summarize data on an ordinal level (with the exceptions of Elopomorpha, Carangia,

Fig. 2 Phylogenetic distribution of care in the bony fishes. Phylogeny of Osteichthyes showing higher-level patterns in the distribution of care and mode of fertilization. Groups are listed on the ordinal level except in cases of limited phylogenetic resolution (*sensu* Betancur-R. *et al.*, 2017). Shaded bars represent the relative frequency of care behaviors at the family-level within each group. The number of families for which care data are available is indicated, along with the total number of families per group. Phylogeny is based on Betancur-R. *et al.* (2017). Reproduced from Betancur-R R., Wiley, E.O., Arratia, G., 2017. Phylogenetic classification of bony fishes. BMC Evolutionary Biology 17(1), 162. doi: 10.1186/s12862-017-0958.-3.

Eupercaria, Ovalentaria, *sensu* Betancur-R *et al.* (2017)). A more detailed analysis of evolutionary trends in the parental care of fish will be published elsewhere.

The Evolution of Parental Care in Fish

Several explanations have been proposed to explain both the ecological and phylogenetic distribution of care behaviors in fish (e.g., Gross and Sargent, 1985; Wourms and Lombardi, 1992; Goodwin *et al.*, 1998; Ah-King *et al.*, 2005; Mank *et al.*, 2005). Here we review several prominent theories and their implications for understanding the evolution of parental care.

Anisogamy

Anisogamy, a reproductive system characterized by differentially-sized male and female gametes, has traditionally been invoked to explain sex differences in parental care and the widespread existence of maternal care across many animal species (Liker *et al.*, 2015). Whereas females typically invest large amounts of energy into egg production, sperm production by males is relatively inexpensive (Liker *et al.*, 2015). Trivers (1972) argued that the large initial investment by females in gamete production should encourage additional investment after fertilization. Despite its popularity, this argument has been criticized on both theoretical and empirical grounds (Dawkins and Carlisle, 1976; Kokko and Jennions, 2008; Liker *et al.*, 2015), as optimal decision making should be based on future costs and benefits, not past investment (Kokko and Jennions, 2008). Additionally, while the anisogamy argument predicts higher frequencies of maternal care (compared to paternal care) resulting from females' costly gametes, this prediction fails to explain the prevalence of male care in fish.

Anisogamy can, however, indirectly influence the distribution of care, as it generally creates a male-biased operational sex ratio in which males are nearly always available to mate, whereas females typically require more time to replenish their egg supply following fertilization (Kokko and Jennions, 2008). In a scenario in which females are scarce due to their reduced potential reproductive rate, the opportunity for additional matings by males may be limited. Under such conditions, recently mated males may enhance their reproductive success by caring for a current brood instead of seeking new mating partners (Kokko and Jennions, 2008).

Aquatic Environment and External Fertilization

One of the primary factors that sets fish reproduction apart from that of most other animals is the fact that it takes place in an aquatic environment. While aquatic species can release free-swimming gametes into the water column, terrestrial reproduction requires internal fertilization to ensure gamete motility (Gross and Sargent, 1985). Our analysis shows that external fertilization is the dominant mode of reproduction in fish (Fig. 2), and highlights a clear pattern of sexual dimorphism in care behaviors. External fertilization without care has independently given rise to male care at least 22 times within the ray-finned fishes, while males provide care in only three families in which fertilization is internal: Apogonidae, Pantodontidae, and Cottidae (included in Fig. 2 under Eupercaria, Kurtiformes and Osteoglossiformes, respectively) (Gross and Sargent, 1985). Conversely, maternal care has arisen only three times from external fertilization in the ray-finned fishes, but represents close to 90% of care in internal fertilizers (Gross and Shine, 1981; Mank *et al.*, 2005), highlighting a strong association between fertilization and parental care in this group. Interestingly, internal fertilization is found in all Chondrichthyans (sharks, skates and rays), and there are no instances of male parental care in this group (Wourms and Lombardi, 1992).

Recent phylogenetic work has rejected the hypothesis that biparental care serves as an evolutionary stepping stone from male-only to female-only care, a widely held notion in the latter half of the 20th century (e.g., Gittleman, 1981). Rather, data suggest two major evolutionary pathways from the basal state of external fertilization and no care: either male care evolves directly from this state, or internal fertilization evolves, followed by female care (Mank *et al.*, 2005).

Certainty of Paternity

Parental care is not expected to evolve under conditions in which the parent has a low likelihood of genetic relatedness to his or her brood (Kokko and Jennions, 2008). Both males and females, therefore, are expected to be more likely to invest in offspring when parentage is assured. The theory of reproductive optimization predicts that males should reduce their investment in a brood of doubtful paternity only if they can ensure a higher confidence of parentage in future broods (Kokko and Jennions, 2008). When paternity confidence varies across broods, fish can dynamically discriminate their reproductive investment based on perceived paternity. Research on bluegill sunfish indicates that males adjust their level of parental care based on olfactory and visual cues of cuckholders and fry (Neff, 2003).

When one looks more closely at externally fertilizing species, a striking pattern emerges. Paternal care is prevalent in pair spawners, in which a single male and female mate by releasing their gametes externally, but absent in group spawners, in which multiple males and females release gametes at the same time (Ah-King *et al.*, 2005). The simultaneous release of gametes in group spawners reduces confidence in paternity, and is thought to retard the evolution of parental care (Ah-King *et al.*, 2005). The potential relationship between parental investment and mating system is particularly intriguing, as the latter can vary widely across a single species and is linked to ecological parameters (Emlen and Oring, 1977), suggesting that environmental factors may indirectly influence care behaviors.

Territoriality

The anisogamy argument has also been used to explain the abundance of territorial males in nature (Kokko and Jennions, 2008). Females are reproductively limited by gamete production, whereas males are mate-limited. By controlling a prime breeding site, a male can attract multiple females and thus increase his mating success. When males actively defend territories, the guarding of eggs may not require significantly more energy or limit additional mating opportunities (Gross and Sargent, 1985), making it a cost-effective means of increasing offspring survival. Territoriality also increases a male's confidence in the paternity of his guarded eggs (Ah-King *et al.*, 2005), and while sneaker or satellite males may successfully fertilize a proportion of a territorial male's clutch in some species, the sneaker fertilization rate is typically much lower than that of the dominant male (DeWoody and Avise, 2001). If territorial males mate with multiple females, females are expected to be less likely to engage in care, due to their reduced relatedness to the genetically mixed clutch (see [Section Certainty of Paternity](#)).

Internal Fertilization

While internal fertilization is a derived state in fish and requires extensive specialization, it can provide greater reproductive security, especially in unpredictable habitats or fast-moving waters such as streams (Meyer and Lydeard, 1993). Under such conditions, the evolution of sperm localization toward potential mates, and ultimately internal fertilization, has clear adaptive benefits. Once internal fertilization has evolved, the progression to female care is achieved by extending the time that the female retains the eggs after fertilization (Rosen, 1962). Prolonged egg retention and viviparity (live birth) are thought to evolve when predation risk is high and resources for young are scarce, enhancing offspring survival at the life stage when mortality is highest (Stearns, 1976). Internal fertilization can also reduce energetic investment in both male and female gonadal development, as fewer gametes are needed to ensure successful fertilization when sperm are transferred directly to eggs (Buckland-Nicks and Scheltema, 1995). Maternal care through egg retention in its most primitive form is lecithotrophic, a form of care in which offspring are provisioned solely by the yolk. In more advanced forms of care, females may provide a supply of nutrients to the offspring from fertilization until their release (i.e., matrotrophy; Wourms, 1981; Wourms and Lombardi, 1992; Reznick *et al.*, 2002).

Maternal Care in Fish: The Exception Proves the Rule

Poeciliidae

While maternal care is relatively uncommon in most families of bony fish, it is the norm rather than the exception in the poeciliids, a group of close to 350 freshwater species (Froese and Pauly, 2017). Nearly all species in this family (which includes the well-known guppies and swordtails) are viviparous, and poeciliids have evolved a specialized placental organ that is similar in both structure and function to the well-characterized mammalian placenta (Reznick *et al.*, 2002). The high incidence of female care in poeciliids may represent a strategy to minimize reliance on a limited resource (i.e., spawning and nesting territory) through internal fertilization and gestation of young. Comparative work indicates that placentation in poeciliids is correlated with increased reproductive output during early life and shorter interbirth intervals, highlighting the potential benefits of maternal care in this group (Pires *et al.*, 2011).

Chondrichthyes

Viviparity (live bearing) has also evolved repeatedly in Chondrichthyes, the cartilaginous fishes, where over half of all species are live bearers, whereas the phenomenon occurs in less than 3% of Osteichthyes (Wourms and Lombardi, 1992). Chondrichthyan eggs are non-buoyant and thus unsuited for pelagic environments, and as many chondrichthyans are physiologically limited in the number of eggs they can produce, the transition to viviparity is not thought to be associated with a significant loss in fecundity (Wourms and Lombardi, 1992). Higher survival rates of live-borne offspring suggest a clear selective advantage for viviparity in this group. Internal egg development enables viviparous sharks and rays to colonize pelagic zones that are unavailable to egg-laying relatives (Wourms and Lombardi, 1992).

Proximate Mechanisms of Parental Care

While parental care has evolved independently multiple times in the bony fishes, caring species exhibit physiological similarities in the function and maintenance of care behaviors. Recent research has targeted hormonal, neural, and social control as three major proximate mechanisms underlying parental care in the group.

Hormonal Control

Prolactin

The hormone prolactin influences a wide variety of functions across vertebrates, and is particularly well known for its regulatory role in human pregnancy and milk production (Freeman *et al.*, 2000). In line with its regulatory activity in the mammalian placenta, prolactin is an important molecule in producing and maintaining the placenta-like brooding pouch in male seahorses. Male pregnancy in the seahorse is under the control of the prolactin-producing pituitary gland, and the detrimental reproductive effects induced by the removal of the pituitary are diminished following the experimental administration of prolactin. Similarly, female

pregnancy in *Gambusia poeciliids* appears to be under pituitary control; removal of the gland in early pregnancy causes almost complete offspring mortality, however no significant effects result from its removal in late pregnancy (Chambolle, 1964). Prolactin has also been shown to play a role the production of mucous, an essential component of offspring protection and nutrition in many types of piscine care (Whittington and Wilson, 2013). The multifunctional prolactin has been implicated in many other forms of fish parental care, including fanning, mouthbrooding, and guarding (reviewed in Whittington and Wilson (2013)).

Androgens

Androgen sex steroid hormones such as testosterone play an important role in the regulation of male reproductive traits. These hormones are often associated with male aggression and are thought to be antagonistic in regard to caring behavior (Scobell and MacKenzie, 2011). Indeed, 11-ketotestosterone decreases when males enter parental phases in many fish species (Páll *et al.*, 2002), and the hormone is not detectable in nesting plainfin midshipman males during offspring care (Knapp *et al.*, 1999). Similarly, male syngnathids (seahorses and pipefish) exhibit a decrease in androgen levels during brooding (Scobell and MacKenzie, 2011). In other species, however, manipulation of androgen levels does not appear to affect paternal care (Ros *et al.*, 2004; Dey *et al.*, 2010). The simultaneous maintenance of both high androgen levels and parental care in some species but not others suggests that endocrine pathways may be utilized differentially across species.

Neural Control

Evidence from cichlid fishes indicates that parents employ distinct visual and chemoreceptive cues to recognize their young depending on offspring life stage (Dulac *et al.*, 2014; Myrberg, 1966). While brain circuitry underlying parental behavior appears to involve conserved neural regions across vertebrates (Weitekamp and Hofmann, 2017), neural modulation of care in fish is still not well-characterized. Parental behavior is regulated in part by the preoptic area in the brain, a region that modulates the expression of the neuropeptides vasotocin and isotocin and has been implicated in care and bonding behavior in mammals (Bass and Grober, 2001). Many species of fish exhibit differential expression of preoptic vasotocin depending on reproductive status (Bass and Grober, 2001), and the disruption of preoptic isotocin receptors in male convict cichlids eliminates paternal care (O'Connell *et al.*, 2012). The mammalian homologues of vasotocin and isotocin (vasopressin and oxytocin, respectively) also play a key role in regulating parental care (Dulac *et al.*, 2014), highlighting the convergent neural pathways underlying parental behavior in vertebrates.

Social Control

Individuals of many species of fish show two or more reproductive phenotypes across their lives. Transformations of sex and dominance in such species can have significant implications for the control of parental care mechanisms, as these plastic identities are often associated with distinct forms of care (Bass and Grober, 2001), suggesting that care may be socially regulated. Male fish in many species start out as non-caring sneaker or satellite morphs, relying on huge gametic output to covertly fertilize eggs without the knowledge of the female or dominant parental male (Taborsky, 1994; see discussion above). Reproductive tactics in such species are often socially dependent, however, and the removal of the dominant male can create a cascade of sexual changes within a social group in which a subordinate individual, whether female or sneaker male, will quickly develop physically and behaviorally into the dominant male (Bass and Grober, 2001). The ability to transform a suite of reproductive characteristics including care based on social cues suggests that parental behavior in such species may be highly labile. Fish displaying alternative reproductive tactics are ideal candidates for exploring the mechanisms underlying parental care, owing to their context-dependent morphs that can be experimentally manipulated.

New Methodologies, New Perspectives: The Cichlid Model

Cichlids (Family Cichlidae) have proved to be a remarkably useful system in which to explore both the proximate (immediate biological) and ultimate (long-term evolutionary) causes of parental care. This family comprises over 1300 species and boasts a wide range of care types including nest-guarding, ectodermal feeding, and mouthbrooding and exhibits male, female, and biparental care (Blumer, 1982; Goodwin *et al.*, 1998). Social and reproductive behaviors vary broadly as well; care has been found in monogamous and polygamous species, and in single-pair breeders and cooperative groups (Goodwin *et al.*, 1998; Taborsky, 2016). Perhaps most significant, decades of scientific interest in cichlid evolution and behavior has resulted in a plethora of data and molecular tools that can be used to investigate key aspects of parental care in this group. Such studies have led to the characterization of behavior, ecology, and phylogenetic history in many cichlid species (e.g., Axelrod and Burgess, 1988; Brawand *et al.*, 2014; Brichard, 1989; Gashagaza, 1991), enabling the elucidation of drivers and consequences of parental care (Goodwin *et al.*, 1998; Kolm *et al.*, 2006). In a recent illustration of the power of a comparative approach, Kolm *et al.* (2006) mapped reproductive traits onto the cichlid phylogeny and found that contrary to model predictions, the duration of parental care in cichlids correlates not with egg size, but rather with the total number of offspring in a clutch.

Cichlids also show the highest frequency of cooperative breeding, a form of reproduction in which offspring are cared for by both parents and non-parental helpers (Taborsky, 2016). Parental and helper behaviors in lamprologine cichlids are ecologically

dependent and influenced by a range of factors such as predation threats and territory availability (Taborsky, 2016). Long-term field and laboratory studies and experimental manipulation in this system have provided a detailed understanding of intricate relationships such as task specialization and reciprocal trading among group members (Taborsky, 2016).

The recent sequencing of multiple cichlid genomes has significantly enhanced our understanding of the highly diversified East African cichlids, highlighting genome duplication and accelerated evolutionary rates as drivers of rapid adaptive radiations (Brawand *et al.*, 2014). Parental care has been cited as one of the components of cichlid biology conducive to rapid speciation (Henning and Meyer, 2014). Genomic tools are likely to be instrumental in establishing a more mechanistic understanding of reproductive behavior (i.e., Bendesky *et al.*, 2017), and the combination of detailed ecological data and genomic resources makes the cichlids an ideal candidate for such work.

In a particularly elegant recent study, Juntti *et al.* (2016) used a multipronged approach to demonstrate the biochemical, neural, and genetic pathways underlying reproductive behavior in *Astatotilapia burtoni*, a mouthbrooding cichlid. The authors experimentally demonstrated that injection of prostaglandin (a hormone-like lipid) induced spawning behavior in non-fertile females. Next, they identified the neural circuitry responsible for signal production and characterized how prostaglandin acts on the brain. Finally, they used CRISPR/Cas9 gene editing to delete the prostaglandin receptor gene, which prevented female spawning. This study illustrates the value of applying cutting-edge molecular tools to dissect reproductive behavior: by taking advantage of the cichlid's laboratory tractability, physiological data, and genomic resources, researchers characterized a pathway linking gene activity to reproductive behavior.

Conclusion

The cichlid model highlights potentially fruitful strategies for other groups of fishes. Recent work on the mechanisms of parental care in this group has combined genomic, hormonal, neural, and behavioral tools, illustrating the multimodal network of controls underlying complex reproductive behaviors (Fig. 3; e.g., O'Connell *et al.*, 2012; Juntti *et al.*, 2016). The combination of detailed studies of functional and physiological mechanisms of care in a small number of model systems, coupled with higher-level

Fig. 3 The cichlid system as a model for the study of parental care in fish. We outline three key elements of the cichlid system that have been integral in establishing this group as a model for parental care. (A) A well-characterized phylogeny provides a solid foundation for the comparative analysis of life-history data (e.g., phylogeny of Tanganyikan cichlids after Meyer, B.S., Matschiner, M., Salzburger, W., 2015. A tribal level phylogeny of Lake Tanganyika cichlid fishes based on a genomic multi-marker approach. *Molecular Phylogenetics and Evolution* 83, 56–71). (B) Ecological diversity of care allows the precise characterization of the proximate and ultimate drivers of care (e.g., biparental mouthbrooders). (C) The application of new methods (e.g., genomics, CRISPR, neurobehavior) facilitates experimental manipulation, clarifying the underlying genetic mechanisms of care behaviors (e.g., the CRISPR/Cas9 method uses a naturally occurring form of immune protection in bacteria to precisely modify target sequences in the target genome; Reproduced from Nødvig, C.S., Nielsen, J.B., Kogle, M.E., Mortensen, U.H., 2015. A CRISPR-Cas9 system for genetic engineering of filamentous fungi. *PLOS ONE* 10(7), e0133085. doi: 10.1371/journal.pone.0133085).

comparative analyses of life-history correlates of care, offer the opportunity to translate experimental results into an evolutionary context, and to link the proximate and ultimate drivers of parental care.

While parental care theory saw great progress in the 1970s and 1980s, new data are contributing to a more nuanced understanding of the evolution of care. We identify three major developments that are likely to play a central role in the future advancement of the field. First, general parental care theory will continue to mature through refinement of mathematical models and empirical testing (Kokko and Jennions, 2008), contributing to a theoretical foundation from which new models of care can be built. Second, sweeping efforts in genome research have begun to resolve contested phylogenetic clades, providing a solid evolutionary context in which to study the origin and diversification of parental care behaviors (e.g., Betancur-R *et al.*, 2013; Betancur-R *et al.*, 2017), and creating new experimental tools for the exploration of reproductive function (e.g., Juntti *et al.*, 2016). Finally, online databases such as FishBase are enhancing the dissemination of a wide range of biological data including information on reproduction and care, and are helping to identify understudied groups worthy of further attention. The continued integration of ecological, evolutionary and molecular data shows terrific promise for clarifying the evolution of parental care in fish and other reproductively diverse groups of vertebrates.

Acknowledgements

We would like to thank Ricardo Betancur-R., Scott Juntti and Michael Taborsky for discussions on the evolution of parental care, and for providing access to unpublished work.

Parental Behavior in Mammals

Toni E Ziegler, Wisconsin National Primate Research Center, Madison, WI, United States; and University of Wisconsin – Madison, Madison, WI, United States

Offspring of mammalian species generally require considerable care since they are born vulnerable to the outside world. Parental investment varies considerably across mammalian species with primarily the main investment occurring from the mother. Only 5 to 10% of mammals show bi-parental care and many of these species are cooperative breeders (Kleiman and Malcolm, 1981). Evolutionarily, females are adapted for extensive parental care and it is much rarer that males care for their young in a direct way (Woodroffe and Vincent, 1994).

In mammals, mothers invest highly in their young since they are specialized to carry the offspring *in utero*, requiring an increased energy expenditure which then is further enhanced following parturition with nursing needs of the infant. The process of birth is especially designed to stimulate sensory stimuli and internal physiological changes in hormones; ensuring brain adaptation and enhancement of maternal – infant bonding. A special form of attachment, the mother – infant bond is where the infant's welfare depends upon maternal care throughout the period of lactation or well beyond this period in some species such as primates (Bowlby, 1969; Ziegler and Crockford, 2017). Primates are very slow to mature and require a heavy investment. In humans, the time to maturity involves an extended period of adolescence where support is still essential (Hrdy, 2009).

This review will discuss parenting in mammals with respect to the mother and mother parenting styles as these have a strong influence upon the offspring. Additionally, the review will extend to the different social structures influencing allocare, or mother's helpers in infant care, as in some species infant rearing requires help, and then on to paternal care behavior, or father's role in offspring development. Behavior is an essential component of any reproduction, especially in promoting successful outcomes of reproduction. One of the complexities of parental care occurs with the psychosocial aspect of offspring attachment and the severe issues that occur with negative parenting on successful growth towards adulthood and subsequent reproduction from the offspring.

Mother – Infant Bonds and Mothering Styles

Hormonal and neural-hormonal mechanisms have ensured that mothers are primed to form strong social bonds with their infants and thereby increase survival (Rilling and Young, 2014). Nurturing behavior from the mother is associated with attachment seeking behavior in the offspring, allowing for a successful mother-infant bond (Broad *et al.*, 2006). However, without the priming of the maternal brain with the hormones of pregnancy, most species of mammals do not show spontaneous maternal care (Keverne, 2005). Studies in rodents have shown that maternal behavior can be expressed in virgin females by repeated exposure to pups, thus sensitization can increase maternal motivation and behavior (Numan and Insel, 2003). Exposure to infants during the juvenile period is important for primates, as they learn about infants and parental care.

The maternal neuroendocrine system responds to the steroidal and peptide hormonal signals coming from the placenta to synchronize birth with maternal care behaviors and milk production for nurturing. Several of the hormones that have been shown to induce changes in the onset of maternal care are prolactin, oxytocin, glucocorticoids and estrogens. Changes in estrogen and its relationship with progesterone are important in mammalian onset of maternal care behaviors (González-Mariscal and Poindron, 2002). Estrogens stimulate the release of oxytocin and prolactin which are both involved in lactation and in mother – infant bonding, Fig. 1.

The maternal brain processes sensory signals from the offspring that stimulates neural activation initiating maternal care of infants. New mothers are attracted to their infant's odors (Fleming *et al.*, 1999). They also respond to their infant's vocalizations, thermal properties, and touch. The accumulation of these cues ensures mothers nurse and protect their offspring and provide them with the appropriate physical and stimulus environment in which to develop.

In primates, hormones may not be essential for primate maternal behavior but promote mother-infant bonding (Saltzman and Maestripieri, 2011). Oxytocin released from the brain coordinates the onset of maternal nurturing behavior at birth in rodents, sheep and primates (Ross and Young, 2009; Ziegler and Crockford, 2017). Since this peptide is conserved over species it is likely to serve the same function in all mammals as is the closely related arginine vasopressin (Ross and Young, 2009). Additionally, dopamine functions in recruiting cortical brain networks for supporting affiliation and is associated with increased dopamine responses supporting the formation of maternal – infant bonds, as dopamine activates the reward system of the brain (Feldman, 2017; Atzil *et al.*, 2017). Under normal environments, maternal care is very rewarding.

Mothering styles have been examined in a number of animal species but the rodent became the primary model for understanding the health and behavioral outcomes of offspring and epigenetics of parental effects (Kappeler and Meaney, 2010). In rodent mothers the different frequency of licking and grooming behaviors towards their pups in the first week of life plays an essential role in establishing behavioral phenotypes in their offspring (Francis *et al.*, 1999). High Frequency Licking and Grooming mothers stimulate and regulate their offspring's endocrine system in a positive manner; thereby influencing metabolism and somatic growth in the offspring (Champagne *et al.*, 2003). Pups from High Frequency Licking and Grooming mothers later show reduced fearfulness and less of a stress response on the output for glucocorticoids from the HPA axis (Hypothalamic-pituitary-adrenal). This is also found by handling a neonatal rat for 15 min daily (Meaney *et al.*, 1991). As adults, these rats

Fig. 1 Schematic of the relationships between the brain and the endocrine systems that regulate maternal behavior. Sensory input from the offspring on the mother acts simultaneous with the hormonally primed neural system to facilitate positive maternal behavior. Changes in the estradiol or the estradiol to progesterone (E/P ratio; decreasing progesterone) stimulate the onset of maternal behavior by activating oxytocin, prolactin, and dopamine. This diagram was adapted from Bridges, R.S., 2015. Neuroendocrine regulation of maternal behavior. *Front. Neuroendocrinol.* 36, 178–196 (10.1016/j.ynrne.2014.11.007).

have a tighter regulation of the secretion of glucocorticoids resulting in lower basal and post stress levels. These “stress hormones” bind to receptors in the hippocampus of the brain which plays a role in regulating the negative feedback regulation of the glucocorticoids release from the adrenal glands (Sapolsky, 2004). Early handling of pups results in adult rats that are more exploratory, less fearful, less reactive to stress and remain much more cognitively intact in their old age (Sapolsky, 2004). These maternal behaviors towards their offspring are translated by environmental effects, or epigenetic, and passed on to the adult pups such that pups from High Licking and Grooming mothers also become High Licking and Grooming mothers as they also pass this trait on to their offspring.

Maternal style also plays a large role in the adult personality of nonhuman primates. Long-term effects of early mothering style, in vervet monkeys (*Chlorocebus pygerythrus*) living in outdoor social groups, have been found on juvenile responsiveness to the external environment (Fairbanks and McGuire, 1988). These studies found that mothering style: either protective or rejecting of their offspring influenced the behavior of their offspring at two years of age. As juveniles, those who had more protective early mothering showed less interest in the external environment while those who had less protective mothers were more likely to explore their environment. The early environment appears to program some aspects of neurobiological development and, in turn, behavioral, emotional, cognitive and physiological development (Sánchez et al., 2001). Many maternal style studies have focused on the laboratory rhesus macaque (*Macaca mullatta*). Rhesus mothers exhibit marked individual differences in anxiety, and such differences are reflected in the differences of their maternal style (Saltzman and Maestripieri, 2011). This nonhuman primate species has been bred in captivity for many years with some of the earliest reports on the effects of social isolation on infants who have been removed from their mothers. Studies performed by Harlow and colleagues have provided actual data showing the need for mother-infant attachment (see Zhang, 2017). Primates need attachments with their mothers to acquire the necessary social skills and to develop normal psychologically and physically.

Cooperative Breeding – Allocare

Cooperative breeding systems occur when non-breeding individuals in the group provide care for the offspring of dominant group members (Lukas and Clutton-Brock, 2017). Very few animals incorporate this breeding system and it occurs only about 1% of the

time. It is associated with social monogamy and the production of multiple offspring per birth, such as twins and triplets. Those in a group that assist in caring for the young of the breeding female are called helpers. They assist in protecting and feeding the offspring. In many cooperative breeding species, few individuals disperse from their natal group or establish new breeding units so may remain in the natal group for extended time. Commonly, the helpers are prevented from breeding, either behaviorally or hormonally, by the dominant breeding female (Clutton-Brock, 2009). Genetic relatedness is high within cooperative breeders and therefore, the helpers are usually older offspring of the breeding couple.

Mammals that have a cooperative breeding form consists of 9 rodent genera (*Cryptomys*, *Heterocephalus*, *Microtus*, *Meriones*, *Rhabdomys*, *Castor*, *Atherurus*, *Peromyscus*), four carnivores (*Alopex*, *Canis*, *Lycaon*, and mongooses) and one in primates (Callitrichidae family, consisting of marmosets and tamarins). The rodents have different levels of cooperative breeding such that some species do communally nursing and mothers are taking care of more than their own offspring (König, 1993). Although house mice are known sometimes to live in monogamous pairs, more typically they occur in small polygynous breeding groups comprising a dominant male, a few females with their litters and occasional additional subordinate males (König, 1993). Canines demonstrate cooperative behavior within social groups ranging from hunting and food sharing to the provisioning of sick adults and dependent pups (Macdonald and Moehlman, 1983). The need for helpers is exhibited in the higher litter mass than with species that exhibit strictly maternal care (Moehlman and Hofer, 1997). Several species of canines have been reported to suppress reproduction in their helpers. The suppression occurs where the breeding female prevents by behavioral means or chemically via olfaction their female helpers in the group from reproducing. The reproductive female in the group needs the helpers to be there for her offspring. This has been demonstrated in captive gray wolves (*Canis lupus*), bush dogs (*Speothos venaticus*), red foxes (*Vulpes vulpes*) and arctic foxes (*Vulpes lagopus*; see Moehlman, and Hofer, 1997).

Among nonhuman primates, the marmosets and tamarins are the most notable for their cooperative care of infants, Fig. 2. However, species of owl (*Aotus sp.*) and titi monkeys (*Callicebus*) also show infant care by older offspring, and therefore, should be considered cooperative breeders (Wright, 1990). The cooperative system allows the species to offset the high costs of reproductive output by limiting maternal investment in each offspring and providing extra-maternal care for the young (Garber and Leigh, 1997). Both the common marmoset (*Callithrix jacchus*) and the cotton-top tamarin (*Saguinus oedipus*) have a postpartum ovulation that occurs as early as 10 and 13 days respectively, following birth (marmosets: Lunn and McNeilly, 1982; tamarins: Ziegler et al., 1990). Conception is high, occurring more than 80% of the time (Ziegler et al., 1987a,b). Therefore, mothers are lactating and pregnant at the same time. This high reproductive rate is energetically costly for mothers, requiring infant care support from the entire family. The ability to simultaneously lactate and conceive, as is seen for the callitrichid monkeys, is due to the lower frequency of suckling due to the lower frequency of nursing bouts allowed by mothers (Ziegler et al., 1990).

Cooperative breeders have delayed dispersal so that offspring of reproductive age forgo their own reproduction to remain in the family and care for younger siblings (Solomon and French, 1997). Cotton-top tamarin daughters are reproductively suppressed while living in such families with no signs of ovulation even though they have gone through puberty (Ziegler et al., 1987a,b). However, in the marmoset species there appears to be a flexibility of response to fertility control in which some families are associated with complete fertility suppression in daughters while in other families many eldest daughters display occasional ovarian cycles (for pygmy marmosets, *Cebuella pygmaea*, Carlson et al., 1997; for common marmosets, Abbott, 1984; Saltzman et al.,

Fig. 2 Family of common marmosets, *Callithrix jacchus*, at the Wisconsin National Primate Research Center. Older offspring remain with their families to learn parenting skills by taking care of younger siblings. Photo by Jordana Lennon, WNPRC.

Fig. 3 Daily urinary hormonal values for a female cotton-top tamarin, *Saguinus oedipus*, demonstrating reproductive suppression while she lived with her family (left side of the graph). Both luteinizing hormone, LH, and estrone-glucuronide were low when living with the family. Once the female was removed and paired with a male (right side of the graph following the black line) she ovulated within 8 days and conceived, resulting in a pregnancy of twins.

1997; Ziegler and Sousa, 2002; for Wied's black tufted-ear, *Callithrix kuhli*, Smith *et al.*, 1997). This may be due to the age of the daughters where those well past puberty are less receptive to the suppressive signals from the mother (Ziegler and Sousa, 2002). While females show suppression of reproductive hormones, males do not. Cotton-top tamarin sons show pubertal hormonal changes while living in the family and even exhibit sexual behaviors but without an appropriate partner (Ginther *et al.*, 2001). A lack of suppression of reproductive hormones in subordinate males has been reported for other species: lion tamarins, *Leontopithecus rosalia* (French *et al.*, 1989) and black tufted-ear marmoset, (French and Schaffner, 1995) and the male offspring of the common marmoset may have a behavioral suppression for sexual behavior (Abbott, 1984) (Fig. 3).

Cooperative infant care for the cotton-top tamarin allows for a buffering of individual parenting styles. Female tamarins do not provide extensive care to their offspring. A female generally spends only around 20% of her time carrying infants in the first six weeks of their life and most of that time is spent nursing infants (Ziegler *et al.*, 1990). Fathers will provide for most of the carrying of infants but as the size of the family increases with more offspring, the amount of a father's carrying time decreases (Washabaugh *et al.*, 2002). Infants receive similar levels of care regardless of group size and parenting experience but the contribution from individual family members will vary with group size and parental experience.

Paternal Care

Parental care by fathers can be essential for the survival and normal development of offspring in biparental species (Saltzman *et al.*, 2017). Father care can involve such behaviors as warming, feeding, protecting, retrieving, and grooming infants. Paternal responsiveness may change across the course of the lifetime in individual males. Likewise, males of some rodent species undergo changes in their behavioral responses to offspring from nurturing to indifference and aggression (Saltzman *et al.*, 2017). In rodents, intra-uterine position during gestation can influence a males' behavioral response to his pups in adulthood (Clark *et al.*, 1998). Fathers who were between two females *in utero* make contact with their own pups significantly more than fathers who were between two males *in utero*. This may be due to different exposure to androgens and estrogens during the gestational period (Vom Saal *et al.*, 1983). Intrauterine position therefore, can modulate the steroids the male is exposed to in early development and shape his behavior towards his offspring.

The care a male receives during his postnatal development, can also have long-term effects on paternal behavior and contribute to stable differences among individuals within a species (Braun and Champagne, 2014). Males that are reared without a father present show less parental care behaviors than do males that are reared with a father present. This is exhibited in spending significantly less time licking and grooming their pups during the first days postpartum (Ahern *et al.*, 2011). Manipulating the levels of parental care received by young males can lead to long-term changes in the male's behavior toward their own offspring (Bester-Meredith and Marler, 2003). Cross-foster studies between parental species, such as the prairie vole and non-parental species such as the meadow vole indicate that male meadow voles raised by prairie voles receive higher levels of parental care and also provide parental care for their offspring (McGuire, 1988). Studies on males that are castrated or intact indicate that mice raised by a castrated father showed less parental care behaviors than mice that had been raised by intact fathers. Additionally, this was associated with changes in arginine vasopressin (AVP) signaling within the brain (Frazier *et al.*, 2006).

Paternal behaviors are associated with response to hormonal changes or behaviors of others can produce hormonal changes. In rodents and primates, there are many studies on the neural endocrine control of paternal behaviors (see [Saltzman and Ziegler, 2014](#)). The hormone prolactin has been associated in rodents and primates with parental care, rising during the mate's pregnancy and after infants are born. A causal relationship has not been established as it has been in birds. However, in the common marmoset it has been shown that prolactin performs as a metabolic hormone ensuring the male does not lose too much weight in his energetic output while caring for infants ([Ziegler et al., 2009](#)). This may be true for rodent fathers as well since in both humans and rodents prolactin is essential for energy homeostasis as it regulates adipogenesis in adipose tissues ([Carré and Binart, 2014](#)). Testosterone levels are typically reduced in fathers during parental care but this has not been a consistent find across all species of rodents and paternal care doesn't always decrease with castration of the father ([Saltzman et al., 2017](#)).

Neuropeptides are also involved in paternal behavior, especially arginine vasopressin, AVP, and oxytocin, OT. In rodents AVP is involved in the expression of paternal behavior and in aggression. It works within the brain to bind to areas such as the lateral septum and the amygdala ([Bales and Saltzman, 2016](#)). Injecting AVP directly into the brain promotes paternal behavior in two species of biparental rodents ([Wang et al., 1994](#); [Parker and Lee, 2001](#)). However, it is not essential for paternal care, indicating that other hormones are involved ([Lonstein and De Vries, 1999](#)). OT is known to facilitate maternal and allomaternal behavior in rodents ([Bridges, 2015](#); [Kenkel et al., 2013](#)). Blocking OT at its receptors does block parental behavior in adult male prairie voles. Additionally, exposure to androgens, estrogens and OT during the postnatal period is important in the expression of paternal behavior in adulthood ([Bales and Saltzman, 2016](#)). Vasopressinergic and possibly oxytocinergic signaling within the brain, is modulated by gonadal steroid hormones, and may represent mediating effects on development and experience that can vary between individuals in paternal care ([Saltzman et al., 2017](#)).

For primates, the mother-infant bond remains important in biparental and cooperative breeding monkeys, but with others to care for the infant, the bond may be strongest with the individual that provides the most care. In the bi-parental species of primates, such as in the titi monkey (*Callicebus moloch*) ([Mason and Mendoza, 1998](#)) and in the common marmoset ([Ziegler and Sosa, 2016](#)), paternal care may also influence infant survival. Extensive research in captivity has shown that a paternal-infant bond in common marmosets exists and the father's involvement plays an important part in the health and wellbeing of his offspring ([Ziegler et al., 2017](#)). Titi monkey males are the primary carrier of infants, with the exception that the mother primarily cares for them during lactation ([Mason, 1966](#); [Mendoza and Mason, 1986](#)). Interestingly, while titi monkey fathers care for infants, studies have shown they lack a selective bond towards their offspring; ([Mendoza and Mason, 1986](#)). Titi fathers show no behavioral or physiological separation distress in response to separation from their infants. In contrast, the infant shows increased vocalizations and plasma cortisol levels. This effect is seen even when the mother is present ([Hoffman et al., 1995](#); [Mendoza and Mason, 1986](#)). As with the titi monkey, father owl monkeys (*Aotus azarai*) contribute extensively to infant care and by the second week postpartum the infant is mainly transported by the father. Males also play with the infant and encourage weaning by food sharing ([Huck et al., 2014](#)). It is possible that the father-infant bond is stronger than the mother-infant bond in certain species.

During marmoset parenting and with other allocaregivers, prolactin is elevated during physical contact with infants ([Dixon and George, 1982](#); [Mota and Sousa, 2000](#)). In hypothalamic explants from the brain, experienced fathers' oxytocin and prolactin levels are significantly higher than levels found in non-fathers ([Woller et al., 2012](#)). Oxytocin stimulates the release of prolactin in the pituitary during reproductive events and there are oxytocin receptors on the lactotrophes that produce prolactin ([Grattan, 2015](#)). Increases in prolactin and oxytocin may promote parenting behavior by interacting with reward centers, and also other social interactions outside of parenting appear to be promoted through similar processes ([Snowdon and Ziegler, 2015](#)). In males, prolactin has important interactions with both estradiol and testosterone, particularly in the contexts of reproductive functioning and parental behavior ([Ziegler et al., 2009](#); [van Anders et al., 2012](#)). Prolactin and testosterone levels have a negative correlation in many animals, including birds, such that prolactin levels decrease and testosterone levels rise during the breeding season, and the reverse occurs during the birthing season ([Logan and Wingfield, 1995](#); [Gubernick and Nelson, 1989](#)). Prolactin's inverse relationship with testosterone levels during parenting has been demonstrated in captive marmosets and humans ([Ziegler et al., 2009](#); [van Anders et al., 2012](#)). When bi-parental males show maternal-like behaviors to their offspring, this coincides with decreased testosterone levels, such as in common marmosets, cotton-top tamarins *Saguinus oedipus*, and humans ([Saltzman and Ziegler, 2014](#)). It is suggested that changes in testosterone levels regulate the secretion of prolactin through a feedback mechanism that is conserved from rats to humans ([Gill-Sharma, 2009](#)). Estradiol enhances prolactin release from the pituitary and increased prolactin lowers testosterone. Dopamine is the main inhibitor of prolactin and is produced in the arcuate nucleus of the hypothalamus ([Freeman et al., 2000](#)). Estradiol has a direct effect on decreasing hypothalamic dopamine and thereby stimulates the release of prolactin, as was demonstrated in a study of marmoset hypothalamic explants from experienced fathers ([Woller et al., 2012](#)).

Since prolactin is involved in the regulation of weight in bi-parental male marmosets and tamarins, this hormone could be the link between affiliation and improved metabolism. Elevated prolactin postpartum, when males are actively caring for infants, may work to prevent excessive weight loss in males during their added energetic demands ([Ziegler et al., 2009](#)). Metabolic regulation of tissue such as the liver, pancreas, adipose tissue and brain all contain prolactin receptors and are regulated by prolactin ([Luque et al., 2016](#)). In pregnant females and during lactation, prolactin promotes fat deposition or mobilization to ensure optimal nutrition for the offspring ([Grattan, 2015](#)). Father marmosets have increased prolactin during body contact with their offspring. This may promote improved regulation of metabolic function during the energetically demanding period of carrying large and heavy infants. Further data is needed on prolactin's role in contact affiliation under different social conditions and between species that express different social patterns and relationships.

Fig. 4 Hormonal changes in (A) estradiol, (B) prolactin and (C) weight gain in male marmosets during their mates' pregnancy. Month 1 is the first month of gestation and 5 is the final month. These males were experienced fathers and all showed increased estradiol, prolactin and weight by the end of the gestation. Weight data has been published in Ziegler *et al.*, 2006. T.E. Ziegler, T.E., Prudom, S.L., Schultz-Darken, N.J., Kurian, A.V., Snowden, C.T., 2006. Pregnancy weight gain: Marmoset and tamarin dads show it too. *Biol. Lett.* 2, 181–183 (10.1098/rsbl.2005.0426).

Common marmosets have extensive physiological responses to the birth of their infants. Expectant fathers display hormonal changes and weight gain in preparation for their offspring's birth during their mate's gestation, [Fig. 4](#) ([Ziegler *et al.*, 2006](#)). Once the infants are born a different pattern of hormonal and weight changes affect the fathers.

Hormonal changes occur in callithricid fathers to help maintain the father's interest in the offspring and to motivate him to parent. The facilitation of parental care comes not only from the hormonal changes that occur in the expectant mother but also with the expectant father. Infants cause physiological changes in their fathers resulting in positive infant care and father – infant bonding ([Prudom *et al.*, 2008](#); [Ziegler *et al.*, 2011](#)). Fathers with dependent infants but isolated from their families, can respond hormonally to their infant's isolated scent secretion ([Prudom *et al.*, 2008](#)). Fathers tested with the scent of their infants show a significant decrease in testosterone levels while cortisol levels do not change ([Fig. 5](#), ([Prudom *et al.*, 2008](#))). When the fathers are compared with the response of naïve males, those who have never been fathers, it documents that this phenomenon is unique to fathers. Naïve males living with a non-pregnant female do not show a response to the infant scent for either testosterone or cortisol.

Further studies indicate that it is not just the reduction of testosterone that occurs to fathers following scent stimuli from their infants, but that simultaneously estrogens elevate ([Fig. 5](#) ([Ziegler *et al.*, 2011](#))). It is likely that a change in the aromatase enzyme that converts testosterone into estradiol is altering to reduce the testosterone in males. Less testosterone ensures a more tolerant parent plus increased estrogens work to increase maternal like behaviors. The influence offspring have on their father's hormones and consequently on their behavior does diminish after they are no longer dependent infants as the same infant scents collected at 3–4 months of age do not produce this effect on their fathers ([Ziegler *et al.*, 2011](#)). The reduced effect is likely due to the rapid reproduction that occurs in the common marmoset. By the time that infants are independent of constant carrying at 3 to 4 months of age, their mother is pregnant again and both mother and father are having hormonal changes preparing for the next set of infants.

Glucocorticoids in male primates appear to function in two main ways related to reproduction: they may facilitate paternal behavior in new fathers ([Nunes *et al.*, 2001](#)) and may promote communication of hormonal states within mated pairs

Fig. 5 Mean androgen and estrogen levels in male marmosets 30 min following smelling an isolated scent from their own approximately 2 week old infant or a novel infant of the same age. These are experienced fathers who show significant decreases in androgen and increases in estrogens in response to infant scent. Data published in Ziegler, T.E., Peterson, L.J., Sosa, M.E., Barnard, A.M., 2011. Differential endocrine responses to infant odors in common marmoset (*Callithrix jacchus*) fathers. *Horm. Behav.* 59, 265–270.

(Ziegler and Snowdon, 2000; Ziegler *et al.*, 2004). Nunes *et al.* (2001) found that male marmosets that frequently carried infants had lower cortisol levels than low carrying males. This result suggests that carrying infants is not extremely stressful but suggests that other stressors may impact both glucocorticoid levels and carrying frequency. Fathers raising their first litters, had higher cortisol levels than fathers raising their second consecutive litters, even without differences in carrying behavior, suggesting that glucocorticoids may help new fathers focus on the appropriate behavioral requirements of the new role (Storey and Ziegler, 2016).

Most reports on oxytocin in non-human primates have focused on pair bonding behaviors rather than on paternal care. However, in one study, intranasal oxytocin increased the tolerance of marmoset fathers when transferring food to weanling infants (Saito and Nakamura, 2011). Most of the work with oxytocin and vasopressin on non-human primates concerned how these hormones affect receptors in particular brain regions (e.g., Kozorovitskiy *et al.*, 2006). First-time and experienced marmoset fathers have a higher density of dendritic spines on pyramidal vasopressin neurons in prefrontal cortex compared to nonfathers (Kozorovitskiy *et al.*, 2006). These results provide evidence for structural reorganization in the prefrontal cortex and a parallel enhancement of vasopressin V1a receptors that indicate plasticity in the brain with parenting experience (Storey and Ziegler, 2016).

Summary

The behaviors of parenting can have a profound effect on the lives of their offspring. Offspring rely on their mothers for survival and for parenting styles they will pass on to their offspring. In the cooperative breeding and biparental care mammals, the care is shared and in biparental species both the mother and father can pass on their parenting styles to their offspring. There are individual differences in both mothers and fathers in parenting and these can influence the health and wellbeing of their offspring.

In both mothers and fathers, and even with alloparental care, hormones are driving parental care as well as responding to sensory signals from others such as the mate and the offspring. The brain and the endocrine act synergistically to create the homeostasis needed in all reproductive events and have been linked evolutionarily to behaviors to influence the next generation. With poor parenting, as in rodents who show lower levels of licking and grooming pups a pattern of poor parental behaviors are passed on can lead to other deficits such as those seen in the primates that can lead to lower social skills.

DEVELOPMENT AND ANATOMY OF REPRODUCTIVE ORGANS

Comparative Sex Organs: Plants

Bharti Sharma and Elena M Kramer, California State Polytechnic University Pomona, Pomona, CA, United States; and Harvard University, Cambridge, MA, United States

© 2018 Elsevier Inc. All rights reserved.

Terminology

Archegonium The female gametangium, a haploid structure that produces female gametes or eggs.

Antheridium The male gametangium, a haploid structure that produces numerous male gametes or sperm.

Embryophytes The lineage of green plants that retain a diploid embryo on the parent's body until it develops into a sporophyte.

Gamete A haploid cell that undergoes fusion to produce a zygote in the context of sexual reproduction.

Gametophyte The haploid multicellular stage of the land plant lifecycle.

Heterospory When the spores are not equivalent, with some spores giving rise to male gametophytes and others, to female gametophytes.

Homospory When the spores are all equivalent in potential and give rise to gametophytes that are hermaphroditic or could be of either gender.

Megaspore A spore that produces a female gametophyte.

Microspore A spore that produces a male gametophyte.

Spore An asexual haploid cell capable of developing into an adult without fusion with another cell.

Sporophyte The diploid multicellular stage of the land plant lifecycle.

Strobili A reproductive axis with specialized leaves bearing sporangia.

Introduction

The lineage “Plantae” includes glaucophyte algae, red algae, green algae and land plants. Representatives of the green algal lineage moved onto land around 470 million years ago and became the dominant inhabitants of the ecosystem (Delwiche and Cooper, 2015). The early land plants evolved a diverse set of characters ensuring successful reproduction. Key among these traits is the basis for their taxonomic designation as the Embryophytes, reflecting the evolution of a diploid multicellular stage of their lifecycle (Grotewold *et al.*, 2015). Land plants are characterized in three major groups: Non-vascular, vascular seedless, and vascular seed plants. This article focuses primarily on sexual reproduction in flowering plants, the largest clade of vascular seed plants which are also called the Angiosperms, but we will also highlight the major reproductive events in bryophytes, ferns and gymnosperms.

As already noted, a shared feature of all land plants is the presence of a multicellular diploid stage, the sporophyte, which is produced in alternation with a haploid multicellular stage, the gametophyte. These two stages comprise the “**alternation of generations**” life cycle (Haig and Wilczek, 2006). Critically, the length of gametophytic and sporophytic phases differs among land plant lineages. In non-vascular plants, the gametophytic phase is dominant while the sporophyte is transient, however, in vascular plants, the sporophyte is dominant and the gametophyte is short-lived. Regardless, the fundamental life cycle is the same: 1. The diploid sporophyte undergoes meiosis to produce unicellular haploid spores. 2. The spores divide mitotically to produce the haploid multicellular gametophyte. 3. The gametophyte use mitosis to produce haploid gametes, either sperm or retained eggs. 4. Male sperm travel to the egg-bearing structure and achieve fertilization. 5. The fusion of the haploid male and female gametes results in a diploid zygote. 5. The zygote undergoes mitosis and matures into the embryo, which gives rise to the multicellular diploid sporophyte (Fig. 1).

Plant reproduction is markedly different from animal reproduction. First, unlike animals, there is no sequestration of the germline during embryogenesis. Instead, the cells that will mature into gametes are recruited from the soma of the gametophyte. In non-seed plants with free-living gametophytes, the specialized gamete-producing structures are called antheridia (producing sperm) and archegonia (producing eggs). With the evolution of the seed, the antheridia are lost as the male gametophyte becomes severely reduced while the archegonium is present in gymnosperms but finally lost in angiosperms. Second, these gametes, being produced in haploid multicellular organisms, are the products of mitosis, not meiosis, which is instead used by the sporophyte to produce haploid spores in organs called sporangia.

Fig. 1 A generalized depiction of alternation of generations in land plants.

Reproduction in Early Land Plants

The earliest diverging lineages of land plants, known collectively as the bryophytes or non-vascular plants, have three major lineages: The liverworts, mosses and hornworts (Shaw *et al.*, 2011). Due to their lack of vasculature and dependence on swimming sperm, these organisms require habitats with ample water. The lifecycle is gametophyte dominant in the bryophytes; the gametophyte is photosynthetic and persistent, providing nutrition to the sporophyte throughout its life. The gametophyte can have a leafy or thalloid structure and typically grows low on the substrate, which can be soil, rocks, or the surface of other plants. The non-vascular plants are homosporous, meaning that they have only one type of sporangium that makes spores of equivalent size. In many taxa, the gametophyte is bisexual and is capable of producing both egg and sperm. However, the liverworts actually have separate male and female gametophytes that are determined by the segregation of sex chromosomes at the time of meiosis in the sporangia. The male gametes are swimming sperm, which must travel to the egg via splashing rain and/or a continuous film of water. When the sperm reaches the egg, the two haploid cells fuse and undergo fertilization resulting in a diploid sporophyte embryo, which is enclosed in the archegonium. In bryophytes, the sporophyte is a relatively short-lived structure. The archegonium initially grows along with the expanding sporophyte but eventually splits into two parts, the upper calyptra, which protects the developing sporangium, and lower vaginula, which surrounds the foot of the sporophyte. The sporophyte itself is composed of three main regions: The foot, seta and capsule or sporangium. The foot is embedded in the gametophyte, arising from the original site of the egg, and mediates nutrient transfer between the sporophyte and parent gametophyte. Mitotic divisions in the stalk-like seta allow it to elongate, raising the distal sporangium into the air column. The sporangium or capsule is where meiosis occurs to produce haploid spores. The capsule eventually breaks open and the spores are released to be dispersed by the wind. The spores will germinate into a filamentous growth, or protonema, which differentiates into a variety of cell types, including chloronema, caulonema and rhizoids. From these filamentous strands, leafy buds will emerge that develop into the gametophores bearing antheridia or archegonia.

Vascular Seedless Plants – Ferns

The reproductive strategy of vascular seedless plants, here exemplified by ferns, is similar to that described for the bryophytes with the critical exception that the sporophyte phase of the lifecycle is dominant rather than the gametophyte stage. Fern gametophytes are very small, typically being photosynthetic and thalloid. On finding a suitable moist surface, haploid spores will germinate into a prothallus or young gametophyte. The gametophyte divides and expands in size into a notched or heart shaped mature structure with rhizoids on the lower surface (Schneider, 2013). Fern gametophytes can be unisexual or bisexual, depending on the light, temperature, and the density of other gametophytes. Male sperm are produced inside the male antheridium and female egg is produced in the archegonium. Upon maturation, the sperm are released and make their way to the egg by swimming. Fertilization occurs inside the archegonium and the zygote matures into a diploid sporophyte. Unlike the sporophyte of the bryophytes, however, this structure will be complex, photosynthetic, and completely independent from its parent at maturity. Fern sporophytes

produce lateral stems called rhizomes that bear clusters of upright leaves and positively gravitropic roots at regular nodes. Sporangia are arranged in clusters called sori, which are commonly positioned on the under or abaxial side of the leaves. In many species, the sori have an outer protective cap or jacket-like covering. Alternatively, sporangia may be grouped together on a common stem and arranged in a tightly packed spiral, termed a strobilus. Inside the sporangia, diploid sporocytes undergo meiosis to form spores. When the sporangium matures, it will crack open to release the multiple spores inside.

Heterospory

While all bryophytes are homosporous, several lineages of vascular seedless plants as well as the entire seed plant lineage have evolved heterospory (Bateman and DiMichele, 1994). There are three critical features of this reproductive system: 1) Heterosporous plants produce separate male and female spores, termed microspores and megaspores, respectively, which differ dramatically in size, consistent with their names; 2) microspores are specifically produced in microsporangia while megaspores are produced in megasporangia; 3) the resultant separate male and female gametophytes, termed microgametophytes and megagametophytes, respectively, are extremely reduced in size and grow to maturity inside the original spore wall, a phenomenon termed endospory. True endospory displays all of these features so, for instance, the sex determination described above for liverworts is not an example of heterospory because their male and female spores come from the same sporangia, are of equivalent size, and produce large, persistent gametophytes.

Seed Plants: Gymnosperms

The evolution of the seed marked a huge shift in the mechanisms of land plant sexual reproduction. The most dramatic changes are to the structures of the male and female gametophytes. The male gametophyte becomes reduced to only two main cell types: The vegetative cell, which is metabolically active, and the generative cell, which will give rise to just two sperm. Furthermore, the microgametophyte no longer releases free swimming sperm. Rather, it has become what we know as “pollen” – a simple cluster of cells that can travel through the air, delivering the sperm nuclei directly to the egg with no need for long distance swimming. The megagametophyte is also radically changed. In heterosporous ferns, the megasporangium releases megaspores that go out into the environment and develop into small, but still free-living, megagametophytes. In contrast, in seed plants, the megasporangia have become indehiscent. This means that the megaspore germinates inside the megasporangium and develops into the megagametophyte within this closed environment. This is the ovule, a modified megasporangium in which the megagametophyte will spend her entire life.

Arrangement of the microsporangia and microspore development: Microsporangia are typically borne on the surface of leaf-like structures called microsporophylls, which are then spirally arranged into a strobilus called a male cone. Inside each microsporangium, each microsporocyte cell divides by meiosis resulting in four haploid spores, which initially remain joined as a tetrad. As the microspores mature, they undergo a limited number of mitotic divisions – essentially germinating and becoming microgametophytes – before they are even released from the microsporangia. During microgametophyte maturation, they acquire a tough outer coating that is impermeable to water and impregnated with sporopollenin, which prevents desiccation and UV damage. These microgametophytes will be released as pollen.

Arrangement of the megasporangia and megaspore development: The megasporangia of gymnosperms are also typically borne on a specialized leaf-like structure termed a megaphyll. Sometimes these are borne singly, as in Ginkgo, but the most familiar gymnosperms arrange their megaphylls in strobili, such as the classic pine cone. In most species, the female cones are larger and longer-lived than the male cones. The megasporangia or ovules are borne on the upper surface of the megasporophylls, often in pairs. Inside each ovule, a single megaspore mother cell undergoes meiosis to produce four haploid cells, of which only one survives and develops into the megaspore. Since the ovule is indehiscent, the megaspore germinates inside the ovule, developing into the megagametophyte of ~1000 cells, including two archegonia.

Fertilization and seed development: Once the pollen has been released, it travels to the ovule, entering a hollow chamber created by leaf-like coverings called the integuments. This chamber, the micropyle, often secretes a drop of fluid, the pollination droplet, in order to better capture windborne pollen. When the pollination droplet evaporates, the pollen grains are drawn into the ovule itself, adjacent to the megagametophyte. In most gymnosperms, the pollen uses tip growth to produce a pollen tube that delivers the sperm nuclei directly to the eggs. However, in the early diverging Ginkgo and Cycad lineages, the pollen grain actually releases swimming sperm, although these only have to travel a tiny distance inside the ovule. Fusion of one of the sperm nuclei with one egg results in a diploid embryo. Critically, this embryo only develops for a short time before entering a dormant stage. During this embryo arrest, the seed develops a tough seed coat and prepares to be dispersed into the environment. On finding favorable conditions, the seed coat breaks and the young embryo emerges to reform a sporophyte with true leaves, roots, and a complex persistent body.

In general, the reproductive process is much slower in gymnosperms than in flowering plants. For example, in the case of pines, micro- and megaspore formation occurs during the first year, followed by pollen release in the second. The formation of the pollen tube, megagametophyte development, and eventual fertilization occurs over a period of months during the second year. Finally, seed maturation and release occurs during the third year.

Reproduction in Flowering Plants the Angiosperms

The diversification of flowering plants into more than 300,000 species approximately 140 million years ago is a fascinating evolutionary phenomenon (Crane *et al.*, 1995; Govaerts, 2001). While many traits are likely to have contributed to their success, the appearance of the hermaphroditic reproductive axes known as flowers, carpels enclosing the ovules, and double fertilization are all important factors. Flowers typically consist of four major organ types: The sterile perianth organs that comprise the sepals and petals, the microsporangia-bearing stamens, and the megasporangia bearing carpels. Similar to gymnosperms, all angiosperms are heterosporous, however, several aspects of their reproduction differ.

Pollen or male gametophyte production: The microsporophylls of angiosperms are known as stamens and consist of two parts, the anther and the filament. The anther contains diploid cells, known as microsporocytes, which divide by meiosis into four microspores. Each microspore then divides by mitosis into a vegetative cell, which eventually builds the pollen tube, and a generative cell, which produces the sperm nuclei. These together form the immature male gametophyte or pollen grain. The pollen is released upon anther dehiscence and is transported to the female gametophyte by animal pollinators or wind.

Embryo Sac or Female Gametophyte Production

As described for gymnosperms, the angiosperms bear indehiscent megasporangia called ovules. However, the ovules are further enclosed by a modified leaf, potentially derived from a megasporophyll, that is known as the carpel. Carpels have three main parts: The ovary containing the ovules, the style through which the pollen tubes grow, and the stigma on which the pollen grains germinate. Megaspore formation inside the ovules is essentially the same as described for gymnosperms, with a lone surviving haploid megaspore. When the megaspore germinates, however, it undergoes only three rounds of mitotic division, resulting in seven cells with eight nuclei. At one end of the megagametophyte, or egg sac, is a trio of cells termed the antipodals while at the other end are the two synergids nestled closely to the single egg cell. In between these cells is the large central cell, which contains two haploid nuclei (Endress, 2011; Friedman, 2006).

Double fertilization: Delivery of pollen onto the stigma can occur via abiotic (e.g., wind, water) or biotic (e.g., birds, bees, moths, bats) pollinators. Once deposited, the recognition of the pollen as belonging to same species may involve coordinated chemical signaling, both from the pollen and the sporophytic stigmatic tissue. In some angiosperm lineages, these interactions also allow the termination of self-pollen, thereby preventing self-fertilization. The pollen germinates by absorbing water from stigma and initiates a pollen tube, which will grow down through the style of the carpel. As the pollen tube reaches the ovary, it is attracted to a specific ovule by chemical signals from the synergids. The tube enters the micropyle of the ovule, triggering degeneration of the two synergids and allowing entry of the two sperm nuclei. Fertilization in angiosperms differs from that of gymnosperms in that it includes two distinct fusion events, known as double fertilization. One haploid sperm nucleus fuses with the haploid egg to produce the diploid zygote while the second sperm nucleus fuses with the two haploid nuclei of the central cell, resulting in a triploid cell. This triploid cell divides to become an angiosperm-specific, nutritive tissue known as endosperm, which will support the young sporophyte embryo in the seed when it is ready to germinate (Friedman, 1995).

From gametophyte to sporophyte: Following double fertilization, the zygote grows into the embryo and undergoes developmental arrest to allow for dispersal of the seed. At the same time, the endosperm matures and takes up nutritional resources from the surrounding sporophytic tissue of the ovule (Fig. 2). In some cases, the endosperm is transient and transfers these nutritional

Fig. 2 Double fertilization in angiosperms.

reserves to the embryos (e.g., peanuts) while in others, the endosperm is persistent (e.g., rice). The seed coat matures into a protective layer to ensure the embryo is safe until it is ready for germination. The surrounding carpel also transforms itself into fruit, which may be fleshy (e.g., a berry), dry (e.g., a capsule) or woody (e.g., a nut). In some cases, the entire fruit is dispersed but in others, the fruit breaks open to disperse seeds individually. Upon germination, the embryo will grow to be the next diploid sporophyte generation.

Overview of Alternation of Generations in Seed Plants

1. Mature **diploid** sporophyte undergoes **meiosis** to produce haploid unicellular microspores and megaspores.
2. The microspore undergoes **mitotic** divisions to produce the male gametophyte, which is composed of a **haploid** vegetative cell and **haploid** generative cell.
3. The **haploid** generative cell will divide **mitotically** to form two **haploid** sperm nuclei.
4. The **haploid** megaspore undergoes three rounds of **mitotic** divisions that result in eight **haploid** nuclei contained in seven cells: Two synergids, one egg cell, a central cell with two nuclei, and three antipodals.
5. Double fertilization results in a **diploid** zygote and a **triploid** endosperm.
6. The **diploid** zygote grows **mitotically** into a next diploid sporophyte generation.

Summary of Sexual Reproduction in Plants

With their tremendous diversity in form, and as the dominant inhabitants of the land ecosystem, land plants have undergone many genetic, developmental and structural changes in reproductive structures over the course of their diversification. The transition from a water ecosystem for green algae to a land ecosystem posed many challenges, including desiccation of spores, secure transfer of male gametes to the female gametophyte, and nourishment and protection of embryo until it matures. Plants evolved the following characteristics to successfully reproduce.

1. A protective covering of sporopollenin around the spores to prevent desiccation.
2. Retention of the zygote in the female parent provided added protection and nutritional support to the young embryo.
3. Differentiation of the gametophyte into male or female. The multiple transitions from homospory to heterospory in early land plants to strictly heterospory in seed plants is associated with both reduced inbreeding and reduction of the gametophyte.
4. Evolution of the seed, which includes both the loss of swimming sperm in favor of a mobile male gametophyte and the evolution of indehiscent megasporangia, which protect the enclosed, reduced megagametophytes.
5. With the evolution of flower, we see the evolution of double fertilization as well as the carpel.

Diverse reproductive strategies allow plants to inhabit ecosystems where other organisms might not survive.

Glossary

Chorioallantoic placenta Placenta of which the fetal components are trophoblast and allantois.

Choriovitelline placenta Placenta of which the fetal components are trophoblast and yolk sac.

Hemotrophic nutrition Exchange of oxygen and nutrients between maternal and fetal blood.

Histotrophic nutrition Supply of nutrients as uterine secretions, cell debris or red cells taken up to the placenta by pinocytosis or endocytosis.

Lecithotrophy Nourishment of the embryo by egg yolk.

Matrotrophy Nourishment of the embryo by maternal sources other than egg yolk.

Oophagy Ingestion of eggs by the embryo.

Placentotrophy The supply of oxygen and nutrients through a placenta.

Viviparity Bearing of live young.

Introduction

Viviparity has evolved in many types of animal. The embryos may be retained in the reproductive tract or some form of breeding chamber, yet rely exclusively on the nutrients provided by the yolk (lecithotrophy). More often viviparity is accompanied by provision of nutrients to the embryo by one or both parents (matrotrophy) (Blackburn, 2015). Matrotrophy takes many forms, but supply of oxygen and nutrients through a placenta is the main focus of this article.

A recent survey found evidence of matrotrophy in 21 of 34 animal phyla (Ostrovsky *et al.*, 2016). It is common in flatworms, arthropods and bryozoans. In arthropods alone, matrotrophy is estimated to have evolved around 30 times. Arrangements for enhancing nutritional transport from parent to embryo take several forms. In velvet worms and arthropods they include placental analogs that mimic vertebrate placentation.

Even among chordates there are several variants of placentation, including the incubation chamber of salps described by Thomas Huxley (Lemaire and Piette, 2015). Salps are tubular animals found near the surface of oceans, where they swim by jet propulsion. The life cycle of salps involves alternation between asexual and sexual generations. The asexual phase (oozoid) develops within the jet chamber of the sexual phase (blastozoid). The placenta consists of two layers separating the embryonic and maternal circulations. Both layers are syncytial and maternal in origin.

Placentation in Anamniotes

Prior to evolution of the cleidoic egg, the yolk sac was the only fetal membrane, but non-amniotes have a long history of placentation. The males of some placoderms, the earliest jawed fishes, had clasper-like appendages, like those of modern sharks, suggesting they practiced intromission of sperm. From intromission, it is but a short step to matrotrophy and placentation. A remarkable fossil from Western Australia shows fetuses one-third of adult body size. This specimen (*Materpiscis attenboroughi*) was so well preserved that it was possible to identify a vitelline cord and show by high resolution computer tomography that it contained blood vessels. Thus viviparity and placentation in vertebrates dates back to the Devonian period, about 380 million years ago (Long *et al.*, 2008).

Cartilaginous Fish

All chondrichthyans, including the basal holocephalans, employ internal fertilization (Hamlett *et al.*, 1993). Many lay eggs but around 55% are viviparous; most of these practice some form of matrotrophy. Examples not involving placentation are oophagy and cannibalism of siblings, which occurs in mackerel sharks. Supplementation of yolk by uterine secretions or histotroph occurs in several species. Thus in sawfish histotroph is secreted by uterine villi. In stingrays, there are elaborate outgrowths from the uterine wall called trophonemata. They secrete lipid-rich histotroph and are also considered important for gas exchange.

There are instances where nutrition is essentially lecithotrophic yet maternal-fetal exchange of blood gases occurs across placenta-like structures. This can be difficult to assess in the absence of functional data. As an example, the embryos of viviparous dogfish derive their nutrition from yolk, but highly vascularized uterine villi act as a source of oxygen, and late embryos use buccal pumping to perfuse their gills and take up oxygen from the uterine fluid. However, modelling of gas exchange in dogfish (*Squalus*

spp.) has shown that oxygen diffusion across the uterine wall cannot provide sufficient oxygen to late stage embryos. Additional oxygen may be supplied through periodic flushing of the uterus with seawater (Tomita *et al.*, 2016).

True placentation occurs in requiem and hammerhead sharks (Carcharhiniformes), where gestation lasts 9–10 months. Initially, the embryo is supported by yolk. When this has been used up, the yolk sac persists and forms a placenta. In the sandbar shark, for example, there are well vascularized elevations of the uterine attachment site that interdigitate with the distal portion of the yolk sac. The uterine secretion products may be similar to yolk proteins.

Bony Fish

Viviparity has arisen in 13 clades of teleost fish including the coelacanth (*Latimeria chalumnae*), a relict of the lobe-finned fish. Studies in viviparous poeciliid and cichlid fish have shown that placentation can evolve quite rapidly.

Teleosts do not possess uteri or oviducts. Ovulation occurs into the ovarian lumen, which is connected to the exterior by a duct opening at the genital pore. Consequently, the embryos of viviparous fish develop either in the ovarian follicle or in the ovarian lumen (Schindler and Hamlett, 1993). In intraluminal gestation, the ovarian lining becomes highly vascularized and secretes histotroph to the lumen where the embryos develop. In goodeid fish appendages called trophotaenia, which protrude from the cloaca, serve as absorptive surfaces. Otherwise absorption of histotroph is through the embryonic gut. In viviparous brotulas (*Ogilbia*) projections from the ovarian lining protrude into the mouth of the embryo (ovarian nipples).

Where development is intrafollicular, the follicular epithelium answers for transfer of nutrients from the maternal circulation to the follicular fluid. Absorptive surfaces of the embryo may be closely apposed to this epithelium forming placenta-like structures. The embryonic component may be the yolk sac. However, in the four-eyed fish (*Anableps*), the pericardial trophoderm develops bulbs that interdigitate with pit-like depressions in the follicular epithelium (Knight *et al.*, 1985).

Viviparity in seahorses and pipefish involves incubation of the embryos in the brood pouch of the male. Analysis of the transcriptome of the brood pouch of the pot-bellied seahorse has identified the genes that are upregulated during pregnancy. Many of the same genes or their homologs are upregulated during pregnancy in mammals (Whittington *et al.*, 2015).

Amphibians

Viviparous species occur in all three orders of amphibians (Wake, 2015). Live-bearing in frogs enables them to abandon their amphibious lifestyle for a more terrestrial one. In the marsupial frogs from South and Central America (Hemiphysactidae), the embryo develops on the back of the mother in either a mucous-filled depression or a closed pouch (Duellman, 2014). The embryos may develop into tadpoles and be released to water-filled cavities in plants or skip the tadpole stage and develop directly into froglets. In embryos of the genus *Gastrotheca*, 1–2 pairs of external gills serve for respiratory gas exchange with maternal tissues in the brood pouch. The gills are shed around the time of birth. A similar strategy has been adopted by frogs in the Neotropical genus *Pipa* (Pipidae) where the eggs develop to tadpoles within individual chambers in the dorsal skin (Fernandes *et al.*, 2011). The chambers become highly vascularized suggesting that gas exchange could occur between mother and embryo. Recently, nutrient transfer from pouch to embryo has been shown to occur in *Gastrotheca* (Warne and Catenazzi, 2016).

Female frogs of the extinct genus *Rheobatrachus* ingested the fertilized eggs and incubated them in the stomach. The developing embryos secreted prostaglandin to inhibit gastric secretion. Male frogs of *Rhinoderma darwinii* ingest eggs and brood the embryos within their vocal sacs; there is evidence in support of nutrient transfer from the paternal circulation to the embryos. There are a few examples of frog larvae developing to froglets within the oviduct, although maternal provision of nutrients other than yolk has been documented only for the Mount Nimba viviparous toad (*Nimbaphrynoides occidentalis*).

Caecilians comprise an order of limbless amphibians adapted for a burrowing lifestyle. They embrace both oviparous and viviparous species. In the former there is extended parental care with the hatchlings feeding on the outer layer of the parent's skin. In viviparous caecilians, the fetuses have teeth and feed on the hypertrophied lining of the oviduct (Wilkinson *et al.*, 2008). A few species of salamander are viviparous. Embryos of the alpine salamander (*Salamandra atra*) ingest unfertilized eggs and feed on the hypertrophied epithelium of the oviduct. Placental analogs have not been described for caecilians or salamanders.

The Fetal Membranes of Amniotes

Whereas placentation in anamniotes often is based on the yolk sac, the cleidoic egg offers three more membranes that can be recruited for placentation (Mossman, 1987; Carter, 2016). These are the amnion, allantois and chorion (Fig. 1(A)). The fluid-filled amnion surrounds the embryo and offers protection from desiccation and mechanical shocks. The allantois is a pathway for gaseous exchange with the ambient air and its cavity is a receptacle for waste. Outermost is the chorion, which in birds and reptiles is situated beneath the egg shell.

Various combinations of these membranes form the basis of placentation in reptiles and mammals (Fig. 1(B)). The chorioallantoic placenta is formed by the chorion and allantois. It is the basis for placentation in viviparous lizards, some marsupials and extant eutherians (known misleadingly as “placental mammals”). The chorionic epithelium constitutes the trophoblast (in mammals the trophoblast). The chorionic mesoderm supplies the blood vessels. The choriovitelline placenta is formed by the chorion and yolk sac. There may be a substantial vasculature. This type of placenta is found in all marsupials. In addition,

Fig. 1 Fetal membranes that contribute to placentation in reptiles and mammals. (A) The amniote egg as in birds, oviparous reptiles and monotremes. (B) Embryo and fetal membranes within the uterus of a generic mammal. The chorion (CHOR) is found beneath the egg shell (ES) in the former and facing the uterine wall (UT) in the latter. In birds and reptiles the other membranes enclose the amniotic sac (AM), allantoic vesicle (ALL) and yolk sac (YS). In mammals and viviparous reptiles, yolk sac and chorion can form a choriovitelline placenta and the allantois and chorion can form a chorioallantoic placenta. Reproduced with permission from Carter, A.M., Mess, A.M., 2014. Mammalian placentation: Implications for animal models. In: McManus, L., Mitchell, R. (Eds.), Pathobiology of Human Disease. San Diego, CA: Elsevier, pp. 2423–2442. © 2014 Elsevier.

non-vascular areas of the yolk sac can play a role in uptake of histotroph in marsupials, viviparous lizards and some eutherians. As described below, viviparous snakes have a third type of placenta derived from the allantochorion and a derivative of the yolk sac.

Placentation in Reptiles

Like birds, the non-avian dinosaurs generally had calcified eggs and fossil evidence of viviparity is restricted to the aquatic ichthyosaurs. Other extinct marine reptiles that were viviparous include archosaurs, mesosaurs and plesiosaurs. Among extant reptiles, neither crocodilians nor tortoises and turtles are viviparous, but live birth does occur in squamate reptiles, including several families of lizards and snakes (Blackburn, 2015; Stewart and Thompson, 2000).

Lizards

In oviparous and viviparous lizards the egg comprises two hemispheres with the chorioallantois covering the embryonic compartment and the yolk sac occupying the abembryonic compartment (Fig. 2). A yolk cleft separates most of the yolk from a smaller portion associated with the yolk sac ectoderm and endoderm (bilaminar omphalopleure). This membrane is a conduit for water even in oviparous species. In viviparous ones the oviduct epithelium facing the yolk sac may proliferate and perhaps secretes histotroph that can be taken up by the yolk sac.

However, in lizards with limited or extensive matrotrophy it is the allantochorion that develops into a placenta. Although four types of allantochorion are recognized it is by no means certain that Types I and II are true placentas (Stewart and Thompson, 2000). Type I occurs mainly in lecithotrophic species and the close association between the yolk sac and uterine epithelium may serve solely for respiratory gas exchange. In Type III, on the other hand, interdigitating folds of maternal and fetal tissues form a placentalome. This has been best described for a number of skinks, including the Italian three-toed skink (*Chalcides chalcides*) and the southern grass skink (*Pseudemoia entrecasteauxii*) from Australia. An even more complex placenta, designated Type IV, is found in a genus of long-tailed skinks (*Mabuya*) from South America (Fig. 3). Altogether there has been convergent evolution of placentotrophy in six clades of skinks. Ample evidence exists for maternal-fetal transfer of nutrients across Type III and IV placentas. In addition electron microscopy has indicated specializations for nutrient transfer even in lizards that are mainly lecithotrophic; these have been characterized as cases of incipient placentotrophy.

Snakes

Some 20% of snakes are viviparous, but since there is no net increase in dry weight from egg to neonate, placental transfer of nutrients may play a limited role in growth of the embryo. So far placentation has been described in just a handful of species.

As in lizards there are two distinct regions of placentation. The chorioallantois is similar to that of lizards. Recent work in water snakes (*Nerodia*) has established that it is specialized for respiratory gas exchange since both the chorioallantois and the apposing

Fig. 2 Extraembryonic membranes of a viviparous lizard, the southern grass skink (*Pseudemoia entrecasteauxii*). The embryonic compartment is enclosed by the chorioallantois, which is apposed to hypertrophied uterine epithelium and the site of nutrient exchange. The bilaminar omphalopleure encloses the yolk. It also faces hypertrophied uterine epithelium and constitutes a yolk sac placenta. Putative sites of placental function are based on functional analysis of differentially expressed genes. Reproduced from Griffith, O.W., Brandley, M.C., Beloiv, K., Thompson, M.B., 2016. Reptile pregnancy is underpinned by complex changes in uterine gene expression: A comparative analysis of the uterine transcriptome in viviparous and oviparous lizards, *Genome Biology and Evolution* 8, 3226–3239. © The Author 2016.

uterine epithelium are well vascularized (Blackburn *et al.*, 2017). The yolk sac placenta of snakes is unique in that the allantois enters the yolk sac cleft and expands to line the inner face of the omphalopleure. The resultant structure is known as an omphalallantoic placenta. It has some ultrastructural features consistent with a role in nutrient transfer.

Placentation in Monotremes and Marsupials

Monotremes are egg-laying mammals, yet two-thirds of embryonic development takes place in the uterus. The embryo is nourished partly by yolk and partly by endometrial secretions taken up through the egg shell membrane. This is porous and able to stretch so the embryo and its membranes increase in size before the egg is laid.

Marsupials are poorly developed at birth and most of their growth occurs as pouch young. The intrauterine phase of development is supported in all marsupials by a choriovitelline placenta and in some by an additional chorioallantoic one (Freyer and Renfree, 2003; Renfree, 2010). A shell membrane persists through the first two-thirds of gestation and the principal source of nutrition is uterine gland secretion. There are vascular and non-vascular parts to the yolk sac and both are able to absorb these secretions. Although exchange of blood gases occurs between maternal capillaries and those of the yolk sac, there is scant evidence of nutrient exchange by that route. A chorioallantoic placenta is found in the koala (*Phascolarctos cinereus*) and in bandicoots (e.g., *Perameles nasuta*). It is supplied by allantoic blood vessels and thought to function primarily as a respiratory organ. Interestingly, chorioallantoic placentation is not associated with greater maturity of the neonate; in bandicoots it may rather contribute to shortening of pregnancy duration. The marsupial placenta generally is considered to be epitheliochorial. However, invasive trophoblast has been described in several opossums (e.g., *Philander opossum*) and in the fat-tailed dunnart (*Sminthopsis crassicaudata*). The marsupial placenta secretes hormones, as evidenced by expression of growth hormone, prolactin and luteinizing hormone genes in the placenta of the tammar wallaby (*Macropus eugenii*) (Menzies *et al.*, 2011).

Placentation in Eutherian Mammals

Unlike in marsupials, the yolk sac plays a subsidiary role in eutherians, while all have a chorioallantoic placenta that supports the fetus to term (Carter and Enders, 2004; Mossman, 1987; Wooding and Burton, 2008). Moreover the trophoblast is invasive except in lower primates and three other orders (Carter *et al.*, 2015). Gestation generally is much longer in eutherians (although shorter in the mouse than the Eastern gray kangaroo). The newborn is better developed than in marsupials, but there is a striking difference between species like the mouse, which give birth to altricial young, and those like the guinea pig that have precocial young. As a rule mammals with precocial young have long gestations and small litters, sometimes just a single newborn, whilst the reverse applies to species with altricial young. There is a remarkable variation in the shape, structure and vascular arrangements of the placenta, but no consistent pattern in relation to gestation length or maturity of the young at birth. Humans are a special case in having a long pregnancy that results in a baby advanced in organ development yet entirely dependent on extended parental care. Portmann coined the term “secondary altriciality” to describe this unique state of affairs.

The remarkable variation in the shape and structure of the placenta is summarized by order in Table 1. As to shape, human placenta resembles a flattened cake; this type of discoid placenta is also found in rodents and several other orders. At the opposite extreme, the diffuse placenta of swine occupies most of the uterine horn and resembles a large sac. In between are the placentas of pecoran ruminants, with a variable number of small discs or placentomes, and the zonary placentas of carnivores.

The arrangement of fetal and maternal tissues in the placenta varies considerably. The most common pattern is a labyrinth. Broadly speaking, fetal capillaries run in one direction and maternal capillaries (or blood channels) in the other, an arrangement that promotes countercurrent exchange. An alternative design has interdigitation of fetal villi with maternal trabeculae that succeeds in minimizing the distance between fetal and maternal capillaries but without countercurrent flow. This is common in the diffuse type of placenta, as in dolphins, and in the placentomes of ruminants. In a small number of species, including catarrhine primates and armadillos, there is a villous tree with fetal capillaries that is suspended in an intervillous space perfused by maternal blood.

Traditionally most attention has been directed to the fine structure of the interhemal barrier and the number of tissue layers separating maternal and fetal blood (Fig. 4). In the epitheliochorial placenta, the uterine epithelium is intact and interdigitates with the trophoblast (Fig. 4(a)). In pecoran ruminants the overall pattern is similar, but a remarkable feature is fusion of binucleate trophoblast cells with uterine epithelial ones to form either a hybrid trinucleate cell (Fig. 4(b)) or syncytium. Some authors refer to this as synepitheliochorial placentation. In endotheliochorial placentas, the only maternal tissue remaining is the capillary epithelium, which frequently is hypertrophied (Fig. 4(c)). Finally, in hemochorial placentas, the trophoblast is directly in contact with maternal blood. The latter may flow in small channels in a labyrinth (Fig. 4(d) and (e)) or perfuse an intervillous space (Fig. 4(f)).

While exchange between maternal and fetal vessels is the principal function of the mammalian placenta, there may be additional supply of nutrients as uterine gland secretions, tissue debris or maternal red cells (Carter, 2012). This is particularly important where the interhemal barrier is epitheliochorial. Thus artiodactyls and perissodactyls have prominent areolae and strepsirrhine primates have chorionic vesicles. These structures contain columnar trophoblast cells arranged in proximity of the mouths of uterine glands and with the ability to phagocytose and process glandular secretions. There are also structures with a more specialized function that take up maternal red cells (hemophagous areas). Such modifications are not confined to epitheliochorial placentas; thus areolae are found in moles and hemophagous areas in tenrecs, both of which have hemochorial placentation.

Table 1 The orders of mammals and the principle characteristics of their placentation including the yolk sac at term

<i>Superordinal clade and order</i>	<i>Common names</i>	<i>Placental shape</i>	<i>Internal structure</i>	<i>Interhemal barrier</i>	<i>Yolk sac</i>
<i>Afrotheria</i>					
Hyracoidea	Hyraxes	Zonary	Labyrinth	Hemochorial	Absent
Proboscidea	Elephants	Zonary	Labyrinth	Endotheliochorial	Absent
Sirenia	Manatees, dugong	Zonary	Labyrinth	Endotheliochorial	Missing data
Macroscelidae	Elephant shrews	Discoid	Labyrinth	Hemochorial	Free
Afrosoricida	Tenrecs, golden moles	Discoid	Labyrinth	Hemochorial or endotheliochorial	Free (large in golden moles)
Tubulidentata	Aardvark	Zonary	Labyrinth	Endotheliochorial	Rudimentary
<i>Xenarthra</i>					
Cingulata	Armillos	Discoid	Intervillous space	Hemochorial	Completely inverted visceral yolk sac
Pilosa	Sloths, anteaters	Discoid or double discoid	Intervillous space (anteaters) or labyrinth (sloths)	Hemochorial (anteaters) or endotheliochorial (sloths)	Absent
<i>Euarchontoglires</i>					
Primates: Strepsirhini	Lemurs and lorises	Diffuse	Labyrinth	Epitheliochorial	Absent
Primates: Haplorhini	Tarsiers, monkeys and apes	Discoid or double discoid	Labyrinth in tarsiers; intervillous space	Hemochorial	Absent
Dermoptera	Colugos	Discoid	Labyrinth	Hemochorial	Free
Scandentia	Tree shrews	Discoid	Labyrinth	Endotheliochorial	Persistent choriovitelline placenta
Rodentia	Rodents	Discoid	Labyrinth	Hemochorial or endotheliochorial	Inverted visceral yolk sac
Lagomorpha	Rabbits, hares, pikas	Discoid	Labyrinth	Hemochorial	Inverted visceral yolk sac
<i>Laurasiatheria</i>					
Cetartiodactyla	Whales, dolphins, even-toed ungulates	Diffuse; cotyledonary in pecoran ruminants	Interdigitating villi	Epitheliochorial	Absent or free
Perissodactyla	Horses, tapirs	Diffuse	Interdigitating villi	Epitheliochorial	Absent or rudimentary
Chiroptera	Bats	Discoid or double discoid	Labyrinth	Hemochorial or endotheliochorial	Free or with inverted visceral yolk sac
Carnivora	Carnivores	Zonary	Labyrinth	Endotheliochorial or hemochorial (hyenas)	Persistent T-shaped visceral yolk sac
Pholidota	Pangolins	Diffuse	Interdigitating villi	Epitheliochorial	Small visceral yolk sac
Soricomorpha	Shrews, moles, solenodons	Discoid; zonary in some moles	Labyrinth	Hemochorial or endotheliochorial	Inverted visceral yolk sac
Erinaceomorpha	Hedgehogs, gymnures	Discoid	Labyrinth	Hemochorial	Inverted visceral yolk sac

Fig. 4 Interhemal barrier of representative mammals. (a) Epitheliochorial placenta of the bush baby (*Otolemur crassicaudatus*). (b) Synepitheliochorial placenta of the cow (*Bos taurus*); note the binucleate trophoblast cells (asterisks) and trinucleate cells (arrows). (c) Endotheliochorial placenta of a bat (*Natalus* sp.); note the enlarged endothelial cells of the maternal capillary in contact with the trophoblast. (d) Hemotrichorial labyrinthine placenta of the mouse (*Mus musculus*). (e) Hemomonochorial labyrinthine placenta of the guinea pig (*Cavia porcellus*). (f) Hemomonochorial villous placenta of an armadillo (*Dasypus novemcinctus*). CYTO TR, cytotrophoblast; ENDO, Endothelium; FC, fetal capillary; MC, maternal capillary; MBS, maternal blood space; MES, enlarged mesenchymal cell; SYN TR, syncytial trophoblast; T1, trophoblast layer 1 (cellular); T2, trophoblast layer 2 (syncytial); T3, trophoblast layer 3 (syncytial); UT EP, uterine epithelium. Based on material kindly supplied by Dr. Allen C. Enders, University of California at Davis, United States. Reproduced with permission from Carter, A.M., Mess, A.M., 2014. Mammalian placentation: Implications for animal models. In: McManus, L., Mitchell, R. (Eds.), Pathobiology of Human Disease. San Diego, CA: Elsevier, pp. 2423–2442. © 2014 Elsevier.

There are no consistent patterns that can explain the variation of the chorioallantoic placenta in terms of parameters such as gestation length or developmental stage at birth. For example, the highly invasive nature of human placentation and the dilated vessels that supply the maternal side of the placenta seem designed to maximize the oxygen supply to the fetus and the fetal brain. But newborn whales and dolphins also have large brains, yet their development is supported by a non-invasive epitheliochorial placenta. It is striking that even-toed and odd-toed ungulates have small litters, long gestations and epitheliochorial placentation. A case can be made that evolution of this placental type conveyed an immunological advantage. On the other hand the African elephant gives birth to a single calf after 22 months, but has an endotheliochorial placenta.

There is further variation in the part played by other fetal membranes in various orders of eutherians. In particular, the visceral yolk sac may persist until term (Carter, 2016). As a rule there has been inversion of the germ layers at an early stage so that the yolk sac presents an absorptive epithelium, the yolk sac endoderm, to the uterine wall as in rodents, lagomorphs and some bats (inverted visceral yolk sac; Table 1). This may be a conduit for the transfer of maternal antibodies that confer passive immunity on the fetus. In many orders, however, the yolk sac is absent at term or is a small sac floating free in the exocoelom (Table 1). Passive immunity may then be conferred by antibodies crossing the chorioallantoic placenta. In orders with epitheliochorial placentation, on the other hand, passive immunity is conferred after birth by antibodies secreted to the colostrum. Finally, in many bats, the yolk sac assumes the morphological characteristics of a gland of unknown function.

Introduction

The female insect is changed by mating. Behaviorally, physiologically, even anatomically, the mated female differs dramatically from her virgin self. In many cases, these changes are induced by proteins and other molecules carried in the male's ejaculate. Exactly how the post-mating phenotype differs from the pre-mating condition varies across taxa, being honed by selective forces that must strike a balance between the male-female cooperation necessary to achieve a successful fertilization, and the broader, often divergent, evolutionary interests of the sexes.

The male reproductive glands, particularly the accessory glands, are tasked with the production of the non-sperm component of the ejaculate (the seminal fluid) in insects. Divergent in number, structure, and developmental origin, they are functional analogues of mammalian glands such as the prostate and seminal vesicles. In this article, we begin by outlining the complexity of insect seminal fluid in terms of both its organization and its molecular composition. Following this, we briefly summarize the general functions of the secretions of male insect reproductive glands, which induce profound changes in female behavior, physiology, and anatomy. As much of our understanding of the activities of seminal fluid components comes from the fruit fly *Drosophila melanogaster*, we pay particular attention to two paradigmatic examples of its seminal fluid proteins, sex peptide (SP) and ovulin, before outlining what is known about another seminal fluid component, the male-transferred hormone 20-hydroxyecdysone, in the malaria vector mosquito *Anopheles gambiae*. We then review the considerable variation in the ultrastructure of reproductive glands across insects, including a detailed overview of *D. melanogaster* accessory glands and their two distinct secretory cell types, the main and secondary cells. Finally, we discuss forces that are thought to have influenced the evolution of accessory glands and their products. This evolutionary framework helps to explain some of the more surprising functions of accessory gland products, such as those that cause female harm.

The Complexity of Insect Seminal Fluid

The ejaculate is composed of sperm and seminal fluid, the latter encompassing a rich diversity of lipids, proteins, carbohydrates, nucleic acids, water, hormones, mucus, vitamins, vesicles, microbes and, in some species, glandular cells. In many insects, the protein component of the ejaculate, derived largely from the male accessory glands, is particularly diverse. To date, 121 accessory gland-expressed genes have been identified in the malaria vector *An. gambiae*, while nearly 100 seminal fluid proteins (SFPs) are transferred to females during mating in another mosquito, the yellow fever vector *Aedes aegypti*. In *D. melanogaster*, over 200 SFPs are known. These SFPs span a range of molecular classes from antioxidants and lectins to proteases and protease inhibitors, the latter two classes being particularly well-represented in both insect and mammalian seminal fluid. In *Drosophila* (and likely in other insects), SFPs' amino acid diversity is further supplemented by a variety of post-translational modifications, such as glycosylation, that may further influence their functions.

Insect ejaculates are generally of two types. First, sperm may be free-swimming within a seminal fluid medium, as in *D. melanogaster*. Alternatively, the ejaculate may be transferred as a spermatophore, as in butterflies and springtails, where both sperm and non-sperm components are encased within a proteinaceous capsule. Spermatophores may adopt complex, multi-layered conformations as in the rove beetle *Aleochara cutula*. In this species, the male secretes a 'tube-like structure' into the female sperm storage organ, which serves to guide the elongation of a secondary tube that will eventually inflate and burst to release sperm.

General Functions of Male Insect Reproductive Gland Products

More than just a vehicle for sperm, seminal fluid components have been implicated in the induction of diverse female post-mating phenotypes. SFPs have been shown to be particularly important in driving these changes, at least in *D. melanogaster*. Roles of SFPs in females can be broadly categorized into those affecting behavior, physiology, or anatomy. Some SFPs also play an important role within the male, by processing other seminal proteins as they pass through the male's reproductive tract *en route* to the female. Others promote activities of the sperm within the female reproductive tract, such as the successful release of sperm from storage.

Modulation of female behavior

After mating, females of many insect species show reduced receptivity to re-mating. This change may be short-term, e.g., just a few days in the Mediterranean fruit fly *Ceratitis capitata*, or permanent, as suggested by some studies of the dengue vector mosquito *Ae. aegypti*. In *D. melanogaster* females, a ~2-week reduction in receptivity post-mating, accompanied by a suite of specific rejection behaviors, is controlled by the SFP sex peptide (SP; see [Section Sex peptide of *Drosophila melanogaster*](#)).

Injection of accessory glands, or their extracts, into virgin females can elicit some of the same phenomena as mating. Many of these effects can also be induced by injecting purified SP into the circulation of virgin females, indicating that the peptide can also

access its targets from the hemolymph. Similarly, in *Ae. aegypti*, injection of accessory gland extracts into the thorax of virgin females or implantation of whole accessory glands prevents re-mating. In *An. gambiae*, injection of accessory gland extracts into virgin females makes them less likely to remate. Furthermore, *An. gambiae* females mated to spermless males (with fully functional accessory glands) exhibit typical changes in post-mating behavior, such as the induction of blood-feeding and mating refractoriness, indicating that sperm are not needed for these responses.

Mating often also causes a change in female feeding behavior. Nutritional geometry experiments in house crickets (*Gryllus bimaculatus*) have demonstrated a shift in dietary preference towards protein-rich food sources following mating. In *D. melanogaster*, SP also elevates female appetite and leads females to favor sodium- and protein-rich food sources.

Modulation of female physiology

In the mated female, seminal molecules affect egg production and ovulation. Consumption of a spermatophore in the two-spot ladybird (*Adalia bipunctata*) is associated with an increase in oviposition rate. This effect is independent of female diet, suggesting that it is driven by molecules from the spermatophore rather than through broader nutritional effects. Injection of male accessory gland extracts into virgin female cotton bollworms (*Helicoverpa armigera*) is also associated with earlier egg maturation and oviposition. In *Aedes* species, increased egg-production is induced by accessory gland extracts. In *D. melanogaster* the analogous effect has been shown to be due to the activity of specific SFPs, such as SP and ovulin, which act through the female's nervous or neuromuscular systems (see [Section Modulation of female anatomy](#), below). An increase in egg-laying has been shown to be a mating-induced effect that is independent of sperm in *An. gambiae*, again suggesting a role for seminal fluid components.

Transfer of SP to *D. melanogaster* females induces an increase in juvenile hormone synthesis. This in turn is associated with diminished female sex pheromone production, vitellogenic oocyte progression, and reduced resistance to systemic bacterial infection. The latter is suggested to reflect trade-offs between investment in reproduction and self-maintenance. Conversely, SP activates expression of genes encoding antimicrobial (AMP) peptides, via the Toll and Imd pathways, perhaps to protect against sexually transmitted microorganisms. SP also influences gut physiology and growth, leading to the production of more concentrated excreta.

Modulation of female anatomy

The SFP ovulin (see [Section Ovulin of *Drosophila melanogaster*](#)) induces visible physical changes in the conformation of the *D. melanogaster* female reproductive tract. By stimulating octopaminergic signalling, ovulin relaxes the musculature surrounding the oviduct. This relaxation leads to the uncurling of a tightly coiled loop in the upper oviduct within 90-min of mating, allowing for transit of an oocyte. Another *Drosophila* SFP, Acp36DE, relaxes a constriction in the upper uterus, facilitating the passage of sperm into storage.

Supporting the activities of sperm

Across insects, ejaculate components can form novel structures within the female reproductive tract. These 'mating plugs' provide a physical barrier to the entry of sperm from rival males, and have been implicated in reducing female receptivity to remating.

In some butterfly species, the mating plug includes an external component that covers the female copulatory opening. In contrast, in some other insects, including *D. melanogaster*, the mating plug sits within the posterior uterus at the distal end of the reproductive tract. The *D. melanogaster* mating plug is bipartite, combining a posterior portion composed predominantly of ejaculatory bulb derived proteins such as PEBme (a protein with some similarity to homopolymer-forming proteins in spider-silk), PEBII, and PEBIII, with an anterior section composed of accessory gland proteins such as Acp36DE. While the posterior component forms within the first 5 min of mating, the anterior section is formed by around 20 min after the start of mating.

Mating plugs also function in promoting sperm storage and retention. The seminal fluid of *An. gambiae* coagulates to form a mating plug in females and is required for the initial entry of sperm into the female storage organs. The *An. gambiae* accessory gland-derived SFP transglutaminase cross-links the SFP Pluglin to form the mating plug, which is slowly degraded in the female reproductive tract over the course of 1–2 days.

Individual SFPs have been identified that regulate the storage of sperm in females. For example, *D. melanogaster* Acp36DE is required for sperm accumulation into the storage organs by 'corralling' sperm and by altering uterine conformation, as noted in [Section Modulation of female anatomy](#). Once in storage, the SFP Acp29Ab, a C-type lectin, is required for the retention of sperm, while the SFPs SP, seminase, CG1652, CG1656, CG9997, and CG17575 are required for efficient release of sperm from storage. In the hymenopteran species *Apis mellifera* and *Atta colombica*, fertility may be promoted by the viability enhancing effect of accessory gland secretions on sperm. However, in polyandrous lineages, this promotion of viability is restricted to self-sperm and actively decreases the viability of rival sperm.

Seminal Fluid Proteins in Focus

Sex peptide of *Drosophila melanogaster*

Transplantation of accessory glands and injection of their extracts into virgin females each initially implicated their products in driving post-mating reduction in female sexual receptivity and elevation of egg-laying. These effects were traced to a 36-amino acid 'sex peptide' (SP) by fractionation experiments and injection of purified sex peptide into the female abdominal cavity, as well as by ectopic expression of SP in transgenic virgin females, and phenotypic characterization of the effects of

RNAi-knockdowns or SP-knockouts. The name ‘sex peptide’ derives from early chromatographic studies by Fox, who noted the presence of male specific peptides in the male body fluid.

SP is secreted by ‘main cells’ into the accessory gland lumen, where it may reach quantities of 3.1pMoles. During mating, mature males transfer between 30% and 50% of the gland’s SP, and are seemingly able to exercise some control over the quantity that they transfer (see [Section Phenotypic plasticity](#)). SP alters the transcriptome of the mated female, significantly changing the level of RNAs relating to immunity, egg development, behavior, early embryogenesis, nutrient sensing, and phototransduction. In females, SP also induces many of the behavioral, physiological, and anatomical effects noted in [Section General Functions Of Male Insect Reproductive Gland Products](#), as well as endocrine changes through activation of juvenile hormone synthesis ([Fig. 1](#)).

SP acts through a G-protein coupled receptor (sex peptide receptor; SPR) primarily in neurons that innervate the female reproductive tract to induce the post-mating change in receptivity. The involvement of additional receptors has also been suggested. While SP’s precise neural targets are not yet known, the ultimate target of its signalling pathway is likely the brain. Targets in the brain may also contribute to the mechanism by which SP reduces daytime ‘siesta’ sleep and elevates aggression towards other females.

While SP is able to induce physiological change in females on its own, its effects are extended in the presence of sperm. Studies in the 1960s noted that the female post-mating response could be separated into a short- and long-term component. The former occurs within the first 48 h of mating and is independent of sperm, while the latter can extend beyond 10 days post-mating but requires sperm (the ‘sperm effect’). It has since been shown that SP binds to both the head and tail of sperm via the N-terminus region of the peptide, a process that depends upon the action of an interdependent network of SFPs. SP’s C-terminus, which induces much of the female post-mating response, is gradually released from the tails of stored sperm by cleavage of SP at a trypsin site by an unknown protease. Stimulation of juvenile hormone synthesis, which is achieved by the peptide’s N-terminus, is thought to be carried out by free SP in the ejaculate, prior to sperm-binding.

Ovulin of *Drosophila melanogaster*

Ovulin, a 264-amino acid prohormone-like seminal protein, is one of the most rapidly-evolving proteins in *Drosophila*. Found in both secretory cell types in the male’s accessory gland, ovulin is transferred to females during mating, where it acts to increase ovulation rate. In particular, it induces the ovulation of mature oocytes that have accumulated in the unmated female, clearing the way for the increased oogenesis triggered by SP.

During mating, some ovulin enters the mated female’s circulation; the remainder stays within her reproductive tract, localizing primarily to the upper oviduct and the base of the ovaries. In the female reproductive tract, ovulin is cleaved by the seminal metalloprotease Semp1. During ejaculation, Semp1 is activated by the serine protease SFP seminase as it transits through the male reproductive tract. Semp1 then cleaves ovulin only after it is transferred to the female ([Fig. 2](#)). Full-length ovulin and two of its cleavage products stimulate ovulation.

Fig. 1 The many effects induced by the seminal sex peptide, in mated female *Drosophila melanogaster*. Modified from Kubli, E., Bopp, D., 2012. *Curr. Biol.* 13, R520–R522.

Fig. 2 The proteolytic pathway that cleaves ovulin. The seminal serine protease *seminase* cleaves the inactive precursor form of the seminal metalloprotease *Semp1* as the two move through the male during ejaculation. This cleavage activates *Semp1*, but the latter only cleaves its target, ovulin, once the proteins have entered the female. Arrows on the diagrams or photographs below the pathway show where the cleavages occur.

Ovulin increases octopaminergic signalling in the female's reproductive tract, although its site of action is unknown. As noted in **Section Modulation of female anatomy**, this leads to relaxation of the oviduct musculature, changing oviduct conformation, thus facilitating ovulation. Although ovulin is only detectable in the mated female for a few hours after mating, its action increases the number of boutons made by octopaminergic neurons on the oviduct musculature. Thus, ovulin's effects can in theory persist long after it has disappeared. However, its effects are only detectable on the first day post-mating; after that, other factors, such as SP activity, account for the increased egg production.

20-hydroxyecdysone of *Anopheles gambiae*

Although SFPs are the major mediator of female post-mating phenotypes in *Drosophila* and most insects that have been studied, in *An. gambiae* the steroid hormone 20-hydroxyecdysone (20E) acts as a major effector of post-mating changes. 20E is a common insect ecdysteroid that regulates molting in juvenile stages and multiple processes in adults, including controlling lifespan, learning, sleep, and social interactions.

An. gambiae males produce 20E in their accessory glands and pass it to the female reproductive tract during mating. Sexual transfer of 20E initiates a series of events that ends with the inhibition of female remating and the induction of oogenesis and oviposition. Furthermore, the mating-induced increase in oogenesis simultaneously decreases the efficiency of the *An. gambiae* immune system to kill the malaria-causing *Plasmodium* parasites.

Within the female *An. gambiae* reproductive tract, degradation of the mating plug occurs over a similar timeframe to the reduction in 20E level. Given that sexual transfer of 20E stimulates oviposition, that large titers of 20E are transferred to females within the mating plug, and the timing of the plug's degradation within the female, it may be that the plug acts as a store of 20E, gradually releasing the hormone following its transfer to females.

Interestingly, mating plug formation and 20E transfer may have coevolved in anopheline mosquitoes. Species that transfer high levels of 20E during mating produce a fully coagulated mating plug, and these species tend to be found in global regions where malaria transmission is high. Conversely, the species that have been studied from areas with low malaria transmission rates neither form a plug nor transfer 20E to females during mating. This has led to the suggestion that the divergent sexual transfer of 20E has influenced the ability of anopheline species to transmit malaria.

The Diversity of Insect Reproductive Glands

A typical insect male reproductive system consists of an ejaculatory duct, with an ejaculatory bulb at its base, and testes and accessory glands branching off from its proximal end. Products of these tissues meet during passage through the ejaculatory duct *en route* to the female.

Across insects, the accessory glands are the most studied contributor to the ejaculate. There is great morphological diversity among these glands (**Fig. 3**), ranging from *Drosophila*'s two lobes to the house cricket's (*Acheta domesticus*) tangled mass of several hundred tubules. Even within a single family, such as *Diptera*, there is considerable morphological diversity of accessory glands.

Species vary in accessory gland number. For example, male mealworm beetles (*Tenebrio molitor*) contain a pair of tubular accessory glands as well as a separate pair of bean-shaped accessory glands, whereas males of *Drosophila* species and the Colorado potato beetle (*Leptinotarsa decemlineata*) each have just a single pair of accessory glands. This morphological diversity is paralleled in the developmental origins of insect accessory glands, which may be ectodermal, mesodermal, or both. Indeed, in the Queensland fruit fly (*Bactrocera tryoni*), males have a pair of highly-innervated, sac-shaped mesoderm-derived glands as well as three or four pairs of spongy, distally bifurcated ectodermic glands.

The cellular complexity of accessory glands is also variable. For example, the bean-shaped glands of *T. molitor* contain seven distinct secretory cell types, whereas the accessory glands of *Drosophila* and *Leptinotarsa decemlineata* contain two and one visibly

Fig. 3 Diagram of the male reproductive tracts of several insects, with reproductive glands shown in blue. Within-tract views are drawn to-scale. As noted in the text, male reproductive glands' developmental origins differ among insects so the blue tissues, although analogous in function, are not necessarily homologous. Drawing by S. Suarez is reprinted from McGraw, L.A., Suarez, S.S., Wolfner, M.F., *et al.*, 2015. *Bioessays* 37, 142–147 with permission.

different cell type respectively. The accessory glands of *Ae. aegypti* have anterior and posterior portions that differ in cell-type and density, as well as in the proteins – and potentially other secretory materials – they produce and contain. Transplantation experiments have demonstrated that the anterior accessory gland cells contain the active molecule(s) that elicit the post-mating female phenotypes of inhibited re-mating and increased egg-laying. Less is known about the posterior cells of the *Ae. aegypti* accessory gland, but they have been suggested to secrete a mucus-like substance that binds granules secreted from the anterior cells.

Different reproductive glands, as well as different cell types in these glands, work interdependently to produce the seminal fluid. For example, the *D. melanogaster* mating plug includes contributions from at least the ejaculatory bulb and accessory glands. In another case, spermatophores in beetles, crickets, and moths are composed of layers derived from the secretions of different reproductive glands. Among species within the suborder *Ensifera*, the 'rough glands' produce the larger spermatophylax component of the spermatophore, while the 'smooth glands' produce the ampulla, which bears the sperm. In the cabbage white butterfly (*Pieris rapae*), both the accessory glands and the distal section of the mating duct contribute to the soft inner matrix of the spermatophore, whereas the proximal region contributes most to the tough outer envelope.

The Accessory Glands of *Drosophila melanogaster*

Each lobe of the *D. melanogaster* male accessory gland is an epithelium that consists of a single layer of ~1000 binucleate secretory cells, encased by a muscular sheath (Fig. 4). The secretory cells belong to two morphologically and biochemically distinct types,

Fig. 4 The *Drosophila melanogaster* male reproductive tract. This drawing, approximately to scale, shows the male reproductive glands and testes. Insets show the position and appearance of the two secretory cell types of the male's accessory glands; nuclei in these binucleate cells are shaded. Drawing by J. Sitnik is reprinted from Gligorov, D., Sitnik, J.L., Maeda, R.K., *et al.*, 2013. *PLOS Genetics* e1003395, with permission.

whose development is differentially specified by the action of Hox, or other homeodomain, proteins. Small, flattened, and hexagonal in shape, the 'main cells' account for 96% of the secretory cells. Main cells produce SP, and several other SFPs including the proteases Semp1, seminase, and CG9997, as well as other proteins important for the binding of the sex peptide to sperm. At the distal tips of the accessory glands, ~40 secondary cells protrude into the lumen. These large, spherical cells contain numerous vacuoles as well as secretory granules and filamentous bodies that resemble structures found among sperm in the female storage organs. Secretion granule-like structures have also been observed in the accessory gland lumens of a number of insects, including species of leafhoppers, bees, and mosquitoes.

Secondary cells produce a cell-type specific set of SFPs including some of those required for the sperm-binding and storage of SP. Unlike main cells, secondary cells continue to grow throughout the life of the adult fly and, in older multiply-mated males, can delaminate from the apical surface of the epithelium, migrate towards the proximal end of the gland, and eventually can be transferred to females in the ejaculate. These processes are under the control of bone morphogenetic protein (BMP) signalling and seem to be accelerated by age (as well as mating frequency). The age-dependent growth and delamination has led to the suggestion that the *Drosophila* accessory gland, and its secondary cells in particular, can serve as a model for the human prostate.

BMP-signalling in the secondary cells also drives the secretion of small, ~30–100 nm diameter, extracellular vesicles (exosomes) and secretory organelles termed dense core granules. Each cell contains ~10 dense core granules, of which approximately 4 are lost during mating and are replenished within ~24 h. Blockage of BMP-mediated secretion in secondary cells impairs the male's ability to decrease remating by his mate, but does not affect his ability to stimulate her egg production. At least part of these effects have been suggested to depend on secondary cell exosomes, which have been reported to fuse with sperm once inside the female and to associate with female reproductive tract tissues. Such fusion could potentially introduce RNAs, proteins, or other molecules to the sperm or female tissues, thereby influencing the female's post-mating response. This model is based on studies in mammals, where the contents of exosomes secreted by malignant cells have been reported to prime nearby tissues for metastatic invasion, and where exosomes from male reproductive tissues have been shown to fuse with sperm and affect sperm activation, capacitation, and motility. These 'epididymosomes' and 'prostasomes' can deliver regulatory RNA species (including tRNA fragments, Y RNAs and microRNAs), as well as growth factors and cytokines, in combinations sensitive to the male's rearing environment and have been suggested to transmit information transgenerationally.

Evolution of Insect Reproductive Glands and Their Products

Several aspects of reproductive gland biology are commonly found among insects: the existence of accessory glands, along with other types of reproductive gland; the biochemical classes of the molecules that these glands produce; and the role of these products in inducing important post-mating responses such as increased egg laying, ovulation, immune gene expression, and feeding. Although many of the effects induced by seminal secretions appear to benefit both sexes in terms of their regulated fertility, some actions of seminal proteins can be deleterious to the female, decreasing her longevity or manipulating her behavior in ways that do not seem to serve her interests. To paraphrase Dobzhansky, in order to fully appreciate the biology of insect reproductive glands, we must understand the forces that have guided their evolution. These forces include:

Sexual selection

Due to their importance for reproductive success, male reproductive processes have been subject to strong and divergent selection. This concept of 'selection in relation to sex' was first laid out by Darwin 12 years after the publication of his theory of evolution by natural selection. 'Sickened' by the peacock's exaggerated plumage, Darwin sought to understand why such elaborate and seemingly deleterious traits can be maintained in populations. His solution came through focusing not on an individual's struggle for survival, but rather on its struggle for matings. Sexual selection theory is built on these conceptual foundations, positing that evolutionary change can be driven by (a) competition between individuals of one sex for access to individuals of the other (intrasexual selection), and (b) preferences held by members of one sex for certain features in the other (intersexual selection).

Post-copulatory sexual selection: Sperm competition

In 1970, Geoff Parker recognized that if a female mates multiply, as occurs in many insect species, a male's reproductive success depends on more than just his ability to compete for a mate. In such polyandrous mating systems, the opportunity for sexual selection continues after ejaculation through 'sperm competition', the competition between sperm from rival males for access to oocytes. In recent years, the development of *Drosophila* lines expressing green- or red-fluorescent proteins in sperm heads has facilitated the visualization of this process in these insects (Fig. 5).

Many traits promote the competitiveness of a male's ejaculate: changes to sperm morphology to promote faster swimming (even including the formation of motility-boosting aggregations), specialized genital morphologies that can physically displace a rival's sperm, or the physical guarding of a female from rival males. Products of the male's reproductive glands also contribute to these phenomena by affecting sperm storage and viability in females, potentially disabling the sperm of a rival, and by a chemical form of mate-guarding: rendering a female unreceptive to remating or stopping her production of 'calling' pheromones, thus preventing other males from being attracted to her.

Post-copulatory sexual selection: Cryptic female choice

The female, however, does not present a passive environment in which sperm competition plays out. Instead, she provides a partisan space in which the outcome of competition between rival males can be influenced in accordance with her own distinct evolutionary

Fig. 5 Visualizing sperm competition in *Drosophila*. Sperm from two males are seen within the seminal receptacle of a doubly-mated female. The heads of the sperm from the first male are green (due to protamine-GFP); from the second male are red (protamine-RFP). Reprinted from Manier, M.K., Belote, J.M., Berden, K.S., *et al.*, 2010. *Science* 328, 354–357, with permission.

interests. This process, therefore, represents the post-copulatory analogue of inter-sexual selection and is named cryptic female choice. Males are expected to evolve mechanisms in response to female choice processes to boost the probability that their sperm will be preferentially retained for use in fertilizations. The roles of seminal fluid components in modulating female insect behaviors (such as sexual receptivity and sperm ejection), reproductive tract conformation, physiology, and immunity were likely shaped by their acting within a dynamic female environment.

Sexual conflict

Selection for traits that promote the success of a male in sperm competition can result in traits that cause collateral damage to females. This is thought to apply in the case of *Drosophila* SP, which limits female remating and thus sperm competition risk, but has toxic effects that shorten the female's lifespan. Additional SFPs, such as the *Drosophila* protease inhibitor Acp62F, have also been shown to be toxic to females.

Conflict can even arise between the interests of males and females long after mating. Individuals have a finite quantity of resources to allocate to reproduction. How a female should best partition these resources across successive breeding attempts depends on factors including mate quality, reproductive experience, and age. For example, her best strategy may be to withhold some resources in a given mating to allocate to her own immunocompetence, foraging ability, and/or somatic maintenance, thus boosting the probability that she survives to mate with a subsequent (possibly more fit) male. However, the optimal outcome for her mate is that she should invest at a high level in their brood, increasing the number or viability of his offspring. Thus, it is often not possible to simultaneously maximize the fitness of both male and female, giving rise to evolutionary tension.

These conflicts can lock males and females into co-evolutionary arms races, each responding over evolutionary time to the other's adaptations. For example, if males transfer seminal fluid components that lead to females over-investing in a current reproductive effort, selection for a counter-response could lead to reduced sensitivity of females to male molecules or mechanisms to neutralize the effects of those molecules. This, in turn, could drive renewed selection on males for new or stronger molecules to produce the male-beneficial effect. More complicated three-way evolutionary arms races arise when selection frees females from male control over their mating rate. This may intensify the degree of sperm competition, selecting for seminal fluid components in males that promote their sperm competitive success, but harm females in the process. These co-evolutionary processes are thought to contribute to rapid evolution in the primary sequence of a significant fraction of SFPs. The arms races may also help explain the diversity of seminal fluid products, evolving in response to female counter-evolution.

The conflicts described occur in the context of a process, reproduction, that also requires cooperation between the sexes: coordination is required between male and female cells and molecules, for egg-sperm binding, or for the processing of certain SFPs in *D. melanogaster* by molecules from both sexes. The extent to which conflict should manifest in reproductive processes will depend upon the degree of asymmetry in the fitness interests of interacting parties. In species with lifetime monogamy (where that monogamy is not enforced by one sex against the evolutionary interests of the other), male and female fitness interests will align closely. Moreover, conflict traits may not evolve even when male and female fitness interests diverge: the extent of the costs and benefits associated with antagonistic traits, as well as the opportunity for such traits to evolve (e.g., presence of sufficient genetic variation), can constrain the manifestation of conflict.

Phenotypic plasticity

Depletion of sperm and SFPs over successive matings constrains male fitness. In *D. melanogaster*, for example, SFP replenishment after mating can take ~3 days. Therefore, selection should favor the male's allocating these products in line with the reproductive context in which he finds himself. Consistent with this hypothesis, males have evolved to strategically allocate sperm and SFPs to females in response to factors such as female mating status, sexual novelty, and quality. In *D. melanogaster*, males transfer less ovulin when mating with recently mated females, but more sex peptide and ovulin when mating in the presence of rival males.

Concluding Remarks

Beyond the sperm and egg, a diversity of seminal fluid molecules are essential for the reproductive success of insects, as in many other animals. Seminal fluid components regulate processes that move sperm through the female reproductive tract and into storage, modify the reproductive tract to facilitate egg production and transit, and influence feeding and digestion to assist in high levels of egg production. Effects of seminal fluid components on females may be beneficial to both members of the mating pair, such as by coupling increased egg production to mating. Alternatively, they may primarily benefit the male, as is likely the case in their induction of female refractoriness to remating. Seminal fluid molecules are produced in male reproductive glands, which themselves vary across insects in number, structure, and cellular constitution. Ejaculate molecules fall into biochemically-conserved classes, but their sequences have come under strong selection to boost reproductive success under sperm competition situations or to co-evolve with reproductive processes in females. Nevertheless, the overlap in molecular and organellar types in the seminal fluid of insects and other taxa makes it increasingly apparent that the study of insect accessory glands provides significant and broad insights into mechanisms of fertility, has implications for our understanding of human male reproductive gland health and disease, and offers powerful opportunities for targeted control of insect disease vectors and pests.

Glossary

Chromatin DNA wrapped around Histone proteins, the modification of which contributes to gene regulation.

Embryo A fertilized egg.

Dynein Molecular motor that hydrolyzes ATP and transports cargo toward the minus-end of microtubules.

Germ plasm Maternally deposited mRNAs and proteins that confer the germline fate, also known as pole plasm.

Kinesin Molecular motor that hydrolyzes ATP and transports cargo toward the plus-end of microtubules.

Maternal-to-zygotic transition A program where the maternal contribution of gene expression ends and zygotic transcription begins.

Microtubules Polarized cytoskeleton polymer comprising α and β -Tubulin dimers.

Nuclear division Mitotic division without cytokinesis occurring within syncytial embryos.

Oocyte The developing egg.

Syncytium A single cell containing multiple nuclei.

Germ Plasm Assembly

Specification of the germline progenitor cells occurs during early embryogenesis. In *Drosophila*, the primordial germ cells (PGCs) are specified about an hour after fertilization through the inheritance of a specialized cytoplasm known as germ (or pole) plasm. Germ

Fig. 1 Progression of PGC development in *Drosophila* embryos. Embryonic stages and approximate time after egg laying (AEL) are indicated. Several genes highlighted in the text as important for PGC development are listed. Embryogenesis commences upon fertilization of the oocyte/egg. At this time, germ plasm (purple) is already localized at the posterior pole. Once syncytial nuclei (grey) are proximal to the germ plasm (stage 3), dynein shuttles germ plasm to surround the posterior nuclei, which are encapsulated by pole buds. By stage 4, PGC cellularization is complete. Programs of transcriptional and mitotic quiescence ensue. Sex determination begins during stage 4, but is completed in late embryogenesis (stage 15 and beyond).

plasm is enriched in maternally-deposited mRNAs and proteins that specify the germline fate **Fig. 1**. The germ plasm is assembled prior to fertilization in the developing oocyte and commences with the localization of *oskar* (*osk*) mRNA, which is both necessary and sufficient to initiate germ plasm assembly (Mahowald, 2001). The mechanisms of *osk* localization are well-studied and entail the transport of *osk* together with associated RNA-binding proteins that function as RNA localization factors, such as Staufen, via kinesin motors. Due to the inherent polarization of the oocyte microtubule network, *osk* becomes enriched to the oocyte posterior pole. Once localized, *osk* and downstream germ plasm components are anchored in place to the posterior actin cortex, the organization of which requires several actin-binding proteins, including Tropomyosin, Moesin, Myosin V, Lasp, Mon2, and others (Tanaka *et al.*, 2011; Suyama *et al.*, 2009; Krauss *et al.*, 2009; Lantz *et al.*, 1999). Deregulation of actin organization is sufficient to impair *osk* localization and germ plasm assembly.

Localization of *osk* mRNA is required for the subsequent translation of Osk protein, which contributes to the anchoring of *osk* mRNA by a positive-feedback mechanism (Mahowald, 2001). Synthesis of Osk protein promotes the recruitment and assembly of other germ plasm components, including the RNA helicase, Vasa (Vas), which functions in piRNA synthesis and is also implicated in translation activation (Lasko, 2013). Subsequent recruitment of *nanos* (*nos*) is needed to silence soma-specific genetic programs, such as transcription, mitosis, and apoptosis to permit germline development (Mahowald, 2001; Hayashi *et al.*, 2004). Upon their localization to the posterior pole, germ plasm mRNAs and proteins are sorted and assembled into ribonucleoprotein (RNP) complexes. RNP assembly promotes the efficient segregation of germ plasm into nascent PGCs by permitting the simultaneous trafficking of multiple RNAs and proteins (Lerit and Gavis, 2011). Not all germ plasm components are trafficked into the PGCs, and proper sorting is essential for germline development (Little *et al.*, 2015). Dysfunction of *osk* localization, germ plasm assembly, or germ plasm passage into the PGCs are all sufficient to disrupt germline development. Historically, many of the original maternal effect sterile mutations (e.g., *osk*, *nos*, and *vas*) were identified by their grandchildless phenotype.

Primordial Germ Cell Formation

One conserved feature of PGCs is that they are typically set aside from the surrounding soma within the first hours of development. Because *Drosophila* embryos are syncytial for the first two hours of embryogenesis, normal development of both the soma and the PGCs requires the sequestration of the germ plasm from nearby somatic nuclei. As embryogenesis proceeds, the syncytial nuclei undergo repeated rounds of synchronous divisions. Concurrently, the nuclei migrate from the center of the embryo towards the cortex. Nuclear division and migration is coordinated by the centrosomes, which are microtubule-organizing centers. Ultimately, nearly 6000 nuclei surround the embryo cortex to form the syncytial blastoderm.

As microtubules propel the syncytial nuclei towards the cortex, a subset of nuclei will contact the germ plasm localized at the posterior pole and initiate the formation of the PGCs (Mahowald, 2001). The physical proximity of centrosomes associated with the migrating nuclei is sufficient to initiate a series of coordinated actin rearrangements that promote the budding of the posterior cortex (Warn *et al.*, 1985) and release of the anchored germ plasm RNPs (Lerit and Gavis, 2011; Lerit *et al.*, 2017). The proximal microtubules serve as tracks for the dynein-dependent active transport of germ plasm RNPs towards the centrosomes, resulting in the enrichment of germ plasm associated with each nucleus within the posterior pole region. This active transport

ensures the majority of the germ plasm is properly partitioned into the PGCs. The posterior nuclei complete their migration into the growing pole buds while continuously recruiting additional germ plasm RNPs until the formation of a contractile ring at the base of each bud completes their cellularization (Warn *et al.*, 1985). Formation of the PGCs occurs during nuclear division cycle 10, whereas the remaining somatic nuclei of the syncytial embryo continue to divide synchronously prior to cellularization at nuclear cycle 14 (Foe and Alberts, 1983).

Functional centrosomes are required for both the formation of the normal number of PGCs and ensuring that the correct quantity of germ plasm is inherited by each cell. The localization of germ plasm to the PGCs is important for two reasons. First, it prevents dilution of the germline determinants, which provide both instructive and permissive signals for germline development. Second, a critical level of germ plasm instructs cell fate. While ectopic germ plasm is sufficient to transform soma into germline, diminished germ plasm inheritance impairs PGC specification and produces cells with somatic characteristics (Lerit and Gavis, 2011).

Specification of Germ Cell Identity

Newly Formed PGCs Differ From the Soma

In addition to precocious cellularization, newly formed PGCs differ from the surrounding soma in several respects. The first difference is mitotic potential. During nuclear cycle 10, the newly formed PGCs undergo 0–2 rounds of asynchronous mitotic division prior to arresting in cell cycle phase G2. *Nos* functions to regulate Cyclin B activity in PGCs and halt their mitotic potential (Mahowald, 2001). In contrast, somatic nuclei of the syncytial embryo complete four additional rounds of synchronous divisions prior to their cellularization at nuclear cycle 14 (Foe and Alberts, 1983). A second difference is transcriptional activity. As in many organisms, early *Drosophila* development is supported by maternally-deposited mRNAs and proteins. The switch to zygotic transcription, the maternal-to-zygotic transition, commences in the soma beginning in nuclear cycles 10–11. In PGCs, however, transcription is attenuated (Nakamura and Seydoux, 2008). Evidence for a global downregulation of transcription in PGCs comes from studies of RNA Polymerase II (RNAPII) regulation (Deshpande *et al.*, 1999; Van Doren *et al.*, 1998). Although PGCs contain comparable levels of RNAPII relative to somatic cells, the RNAPII localized to PGCs lacks key activating post-translational modifications Fig. 2. The phosphorylation status of two serine (Ser) residues within the heptad repeats of the RNAPII C-terminal domain (CTD) serves as an indicator of RNAPII activity (Phatanani and Greenleaf, 2006). Phosphorylation of Ser5 is catalyzed by CDK-7 and likely mediates transcription initiation and promoter clearance. In contrast, phosphorylation of Ser2 is catalyzed by P-TEFb/CDK-9 and mediates transcription elongation. Increased levels of phosphorylated Ser2 and Ser5 in somatic nuclei mark the onset of zygotic transcription, whereas the RNAPII CTD remains largely unmodified in the PGCs. Further transcriptional repression is achieved specifically in PGCs via repressive chromatin marks. Germ cells in *Drosophila* and *C. elegans* lack methylated lysine 4 on Histone H3 (H3meK4), a chromatin mark associated with transcriptional activity (Schaner *et al.*, 2003). The global downregulation of RNAPII-dependent transcription is a conserved feature of embryonic germ cells in diverse organisms, including *C. elegans* and *M. musculus* (Saga, 2008; Seydoux and Dunn, 1997). As opposed to RNAPII-dependent mRNA synthesis, rRNA transcription controlled by RNAPI remains active in both germline and soma, rendering them translationally active (Van Doren *et al.*, 1998). Thus, PGCs exhibit delayed initiation of zygotic transcription and rely on maternally-provided mRNAs and proteins for their specification and development.

Protecting and Promoting PGC Identity

Special mechanisms protect PGCs from the signaling systems that engineer somatic development and differentiation. In the absence of such mechanisms, PGCs may lose their capacity to develop into germline stem cells (GSCs) and enter somatic differentiation. In *Drosophila*, at least two different mechanisms are believed to insulate PGCs from their environment and ensure their eventual progression to GSCs. One of these is the physical sequestration of PGCs from the soma as discussed above in *Primordial Germ Cell Formation*. Another mechanism is mediated by three maternally deposited, cell autonomous factors that impose transcriptional quiescence by downregulating RNAPII activity: *germ cell-less* (*gcl*), *polar granule component* (*pgc*), and *nos* (Leatherman *et al.*, 2002; Martinho *et al.*, 2004; Kobayashi *et al.*, 1996).

Fig. 2 RNAP II activity is downregulated in PGCs. Phosphorylation of Ser5 and Ser2 (pSer5 and pSer2) on the CTD of RNAP II promotes mRNA transcription. (A) Levels of pSer5 (green) are diminished in PGCs (Vas, red) relative to the proximal somatic cells. (B) Levels of pSer2 (green) are significantly reduced in PGCs (Vas, red), but abundant in somatic cells. (C) Table summarizes the relative enrichment of pSer5/2 and the predicted transcriptional output in soma versus germline cells.

To achieve establishment and/or maintenance of transcriptional silencing in PGCs, *gcl*, *pgc*, and *nos* employ distinct mechanisms. Namely, they act at different times during the early nuclear cycles and target an overlapping but distinct set of somatically active genes. For example, *gcl* acts between bud formation (nuclear cycle 10) and nuclear cycles 12–13. Thus, *Gcl* is involved in silencing genes such as *scute*, *sisterless a*, and *runt* that are selectively upregulated in the soma prior to the global onset of zygotic transcription (Leatherman *et al.*, 2002). In contrast, *pgc* and *nos* are required later after the onset of zygotic transcription to block the expression of somatic patterning genes. While *Pgc* encodes a short peptide that functions to inhibit CDK-9 and block transcriptional elongation of targets such as *zen* and *tailless* (Deshpande *et al.*, 2004), *Nos* functions cooperatively with Pumilio to prevent expression of targets such as *even-skipped* and *fushi-tarazu*, likely by repressing the translation of a key transcriptional regulator(s) (Deshpande *et al.*, 1999). Of the three transcriptional regulators, mutations in *nos* have the most profound effects both on transcription and PGC specification. In addition, *Nos* regulates numerous other targets to orchestrate subsequent steps in PGC development and viability.

The fact that *Drosophila* utilizes three distinct factors to inhibit RNAPII supports a model where PGC specification requires a global downregulation of mRNA transcription. Nonetheless, escaper PGCs can form, survive, proliferate, and give rise to a functional gonad in the absence of *gcl* or *pgc*. Although such animals are not completely sterile, they have low fecundity, indicating reduced fitness. On the contrary, germ cell-specific loss of *nos* activity is sufficient to induce sterility, demonstrating an essential role for *nos* in germline development (Deshpande *et al.*, 1999). Although PGCs normally repress RNAPII activity to attenuate mRNA transcription, they do maintain active transcription of rRNA mediated by RNAPI (Van Doren *et al.*, 1998; Seydoux and Dunn, 1997). Because rRNA is an essential component of ribosomes, these findings highlight the role of translational control of gene expression in PGC development.

Primordial Germ Cell Sex Determination

PGCs form far from the site of the future gonad. Upon gastrulation, *Drosophila* PGCs migrate dorsally along the surface of the embryo, invaginate into the midgut cavity, and then undergo trans-epithelial migration across the midgut to find their way through the mesoderm to populate the gonad (Mahowald, 2001). Here, PGCs are surrounded by somatic gonadal precursor cells that support gonad development. Within the gonad, PGCs develop into the germline that gives rise to sex-specific gametes. *Drosophila* sex determination is dependent on the karyotype of the sex chromosomes within somatic cells where XX flies are female and produce eggs while XY flies are male and produce sperm. The number of X chromosomes serves as the key determinant of sexual identity. In contrast, the Y chromosome has no role in sex determination but does function in sperm maturation. In order to give rise to their respective gametes, it is important that sex-specific genetic programs are established during PGC development.

Somatic Sex Determination

Somatic sexual identity is determined downstream of the sex chromosome karyotype and is specified during early embryogenesis prior to gonadogenesis. XX females activate the expression of *Sxl*, the master sex regulatory gene, from an early embryonic promoter, *Sxl-Pe*, at nuclear cycle 12, shortly after PGC formation. This is followed by *Sxl* expression from a late promoter, *Sxl-Pm*, in both sexes at nuclear cycle 14, after somatic cellularization and full activation of the maternal-to-zygotic transition. The presence of *Sxl* protein in XX females potentiates an autoregulatory loop where it binds to *Sxl* transcripts and causes skipping of an exon containing an early stop codon, thus allowing for the continued synthesis of functional *Sxl* protein. *Sxl* transcripts in XY males contain the early stop codon and, therefore, are unable to produce functional protein. A cascade of alternative splicing events involving *Tra*/*Tra2* downstream of *Sxl* eventually produce a female-specific isoform of the transcription factor *Dsx^F*, while the default isoform, *Dsx^M*, is male specific. These sex-specific *Dsx* isoforms instruct the majority of somatic sex differentiation (Oliver, 2002).

Germ Cell Sex Determination

The sexual identity of germ cells is specified by intrinsic signals based on their sex chromosomes, as well as extrinsic signals derived from the surrounding soma. We will first discuss autonomous factors determined by the karyotype, then we will describe the non-autonomous influence of the surrounding somatic cells.

Germ cells with two X chromosomes initiate an autonomous genetic program to promote female sexual identity. The determination of female sexual identity is downstream of a genetic hierarchy starting with the transcription factor *Ovo* (Oliver, 2002). Whereas XX germ cells show high levels of *ovo* expression, XY germ cells show little to no *ovo* expression. Consistent with this finding, *ovo* activity is necessary for XX germ cell viability but is dispensable in XY germ cells. An important downstream effector of *ovo* is the *otu* locus. In females, the high levels of *ovo* activity promotes the expression of *otu*, which in turn regulates the expression of *Sxl* through an unidentified mechanism. Thus, the genetic pathway necessary for specifying female sexual identity is defined by a cascade wherein *ovo* → *otu* → *Sxl* Fig. 3. Consistent with a role in promoting normal germline development, mutations in *ovo*, *otu*, or *Sxl* result in ovarian tumors and are female sterile.

Expression of *Sxl*, the key regulator of female germline identity, normally occurs at embryonic stage 9 in XX PGCs. Induction of female-specific *Sxl* in stage 9 XY PGCs transplanted into XX embryos is sufficient to switch the sexual identity of the PGCs. In contrast, ectopic expression of *Sxl* later during embryogenesis at stage 15 is insufficient to promote female identity in XY PGCs

Fig. 3 PGC sex determination. PGC sexual identity is dependent on the sexual identity of both the PGC and surrounding somatic cells. During female (dark pink text) somatic sex determination, Sxl sets up an alternative splicing cascade eventually resulting in the presence of Dsx[F]. In female PGCs, Ovo promotes female identity and eventually results in the expression of Sxl at the bottom of the hierarchy. Downstream targets of Sxl have yet to be determined. In males (blue text), the absence of functional Sxl or tra (light pink text) results in the default Dsx[M] splicing, which carries out male somatic sex determination. The absence of Sxl in PGCs results in a male germline identity. Other factors, such as autonomous Phf7 and the non-autonomous Jak/STAT signaling cascade, promote male identity in PGCs as well. The interplay between autonomous and non-autonomous signaling has yet to be elucidated, and it is not determined where in the hierarchy these cascades influence each other in both female and male signaling. Arrows indicate signaling cascades, question marks (?) denote unidentified factors.

but results in germline tumors. Thus, the establishment of female PGC sexual identity likely occurs between embryonic stage 9 and 15, but this program cannot completely override the male sex determination pathway once it is established (Hashiyama *et al.*, 2011).

While Sxl promotes the female identity in PGCs during early embryogenesis, Phf7 is a factor active later in development that promotes male sexual identity. Phf7 is expressed around stage 17 of embryogenesis, after the establishment of sexual dimorphism in the germ cells of the coalesced gonad. Phf7 recognizes H3me2K4, a chromatin mark associated with transcriptional activity (Yang *et al.*, 2012).

Supporting the involvement of non-autonomous signaling in germ cell sex determination, aberrant PGC development ensues when they are transplanted into the somatic environment of the opposite sex. For example, XY germ cells surrounded by an XX soma form tumors filled with cells that are morphologically similar to early spermatocytes. By contrast, XX germ cells surrounded by an XY soma fail to develop. Alternative methods to transplantation, aimed at switching the somatic sex by targeting the canonical sex determination pathway at the level of Tra activity, generally mimic the results of transplantation studies (Oliver, 2002). Likewise, overexpression of Phf7 in XX PGCs in a female somatic environment leads to cell death, while expressing Phf7 in XX PGCs that are transplanted into a male soma is sufficient to induce a male sexual identity (Yang *et al.*, 2012).

One significant effector of the somatic sexual identification pathway is the dsx locus. Male and female somatic cells express sex-specific Dsx isoforms. There have been relatively few insights into the somatic factors downstream of sex-specific Dsx isoforms that constitute the extrinsic sex determination cues that influence PGC sexual identity. In males, Jak/STAT signaling promotes an increase in XY PGC cell number, one of the first sexually dimorphic characteristics. Stage 15 male somatic cells express the activating Jak/STAT ligand Unpaired (Upd), resulting in expression of the transcription factor STAT92E in the male germline. Loss of this cascade results in a reduction of XY germ cells. While Jak/STAT signaling is necessary for male PGC development, it is not sufficient (Wawersik *et al.*, 2005). Somatic induction of Upd in female somatic cells is able to activate STAT92E resulting in increased PGC number, however, female germ cells are still maintained and produce viable offspring. Thus, the ectopic somatic influence of Upd is not able to override the female PGC sex determination program. Taken together, these findings suggest that while PGCs are sensitive to sex-specific signals from their somatic environment, such signals alone are not necessarily sufficient to override or reset the cell autonomous sex determination program.

Presently, mechanisms that direct PGC sex determination are little understood. While Ovo activity is predominantly responsive to the germ cell karyotype, it is also influenced by the somatic environment. Somatic signals can also influence PGC sexual identity downstream of ovo. Therefore, it is still relatively ambiguous as to how and when somatic signaling influences germline sexual identity. Additional uncertainty underlies the mechanism of how Sxl defines female sexual identity in PGCs. While Sxl is necessary and sufficient to induce a female genetic program in PGCs beginning at embryonic stage 9, how this alternative splicing factor carries out this function remains unknown. Likewise, the male-specifying factor Phf7 induces a male sexual identity in PGCs later in development, although upstream and downstream regulatory factors remain to be identified. Other sex-specific signals downstream of the canonical sex determination pathway from the surrounding soma, such as STAT92E, also influence PGC sexual identity. But, again, precisely how Jak/STAT influences germline sexual identity is unclear. The interplay between these pathways is currently the

Fig. 4 Cartoon schematic showing the germline versus soma dichotomy. PGCs differentiate from the surrounding somatic cells through distinct regulation of genetic programs and signaling pathways. This table shows a few key differences that distinguish the PGCs from somatic cells (bold text in top row). Many of these differences are evolutionarily conserved among the species illustrated: *Drosophila* (fly), *C. elegans* (worm), *D. rerio* (zebrafish), *Xenopus* (frog), and *M. musculus* (mouse). Animals are not drawn to scale.

main focus of the field. Deciphering the inputs and crosstalk between these signaling cascades will likely elucidate a more comprehensive understanding of PGC sex determination.

Concluding Remarks

The germline-soma dichotomy is established early during embryogenesis of diverse organisms. Specification and isolation of the germline ensures proper determination of the PGCs and also protects the surrounding soma from cell fate transformation. One example of this paradigm is observed through the precocious cellularization of PGCs during the first hours of *Drosophila* embryogenesis. For many organisms, such as *Drosophila*, *C. elegans*, *Xenopus*, and *D. rerio*, the PGCs form following the inheritance of maternally-deposited germ plasm. Other organisms, including *M. musculus* and *Homo sapiens*, form PGCs by inductive cell-signaling cascades (Strome and Updike, 2015). It is interesting to note that despite these differences, many facets of the germline-soma dichotomy are conserved Fig. 4. For example, PGCs display transcriptional quiescence in *Drosophila*, *C. elegans*, *Xenopus*, and *M. musculus* through attenuation of RNAPII activity. Further global downregulation of transcription is achieved by regulating activating or repressive histone modifications, as described in *Drosophila*, *C. elegans*, and *M. musculus* (Lesch and Page, 2012). In addition, most organisms form their germline progenitor cells far from the site of the future gonad, and germline-soma interactions are often necessary to maintain PGCs. Remarkably, many of the genes involved in PGC specification and development are conserved from *Drosophila* to *Homo sapiens*, including *nos* and *vas*. In other cases, discrete protein domains are conserved in functional paralogs. For these reasons, investigation of the core conserved mechanisms of PGC development in tractable model organisms, such as *Drosophila*, continues to shape our understanding of germline formation and function.

Epigenetic Programming of Germline, Nonmammalian Vertebrates

The Germline as a Transmitter of Genetic Code to the Next Generation

In multicellular organisms, the germline, from diploid primordial germ cells (PGCs) to haploid germ cells (sperms or oocytes), is a unique cell lineage that contains all of the genetic information of an individual and transmits it to the next generation. After production, gametes can be fertilized to form a new zygote conferring totipotency and establishing a new organism as progeny. Thus, the germline provides a permanent link between all generations.

Through development from the totipotent zygote to the pluripotent embryo, the embryonic cells differentiate into multiple lineages. Among them, PGCs, which constitute a small population in the early embryo and are clearly distinct from other somatic cells, are the specialized precursors of the germline. PGCs are unipotency, i.e., they contribute solely to produce mature gametes, in contrast to pluripotent stem cells that can contribute to all three germ layers. In this context, specification of PGCs at an early stage has been considered crucial because the germline is important not only for fundamental research, but also for the potential use of genetic resources. As such, when and how the germline first arose are essential questions in developmental and evolutionary biology.

In the animal kingdom, PGCs can be specified from two general modes: preformation and induction ([Strome and Updike, 2015](#)). In preformation mode, germ cells are uniquely determined by cytoplasmic organelles, generically referred to as germ granules or germ plasm. They contain maternally inherited mRNAs, proteins, and small RNAs, which play crucial roles in germ cell specification, including in roundworm, fruit fly, zebrafish, and frog. In contrast, in the inductive mode, which is observed in animals including mouse and human, the germline is initially found in proximal-posterior epiblasts and induced by bone morphogenic protein (BMP) signaling from neighboring extra-embryonic tissue during gastrulation.

After specification, PGCs originating from the extra-gonadal region migrate across the embryo into the developing genital ridge. On settling in the gonad, the germ cells increase rapidly in number and sexually differentiate into spermatogonia and oogonia via intrinsic and extrinsic factors. In males, germ cells undergo mitotic arrest until birth, and spermatogonial stem cells generate sperm through meiotic segregation during the process of spermatogenesis. In females, oogonia are arrested in prophase of the meiosis I cycle until puberty, and then exhibit maturation and the resumption of meiosis to form haploid oocytes in the metaphase of the meiosis II cycle during ovulation. Upon fertilization, the meiotic procedure of females is finally completed. In this way, the infinite cycle of the germline is maintained from generation to generation.

Epigenetics in Germline

Epigenetics is the mechanism underlying spatiotemporal control of gene expression during development without modification of the DNA sequence. The epigenetic status determines the characteristics of cells and tissues, and its alteration can cause the loss of cellular identity or cell fate. The most well-known molecular mechanisms of epigenetic regulation are DNA methylation, histone modification, and post-transcriptional regulation of small non-coding RNAs.

DNA methylation generally involves covalent modification, which occurs predominantly in CpG dinucleotides. Members of the DNA methyltransferase (DNMT) family convert cytosines to 5-methylcytosines (5mC). DNA methylation in the upstream promoter of a gene suppresses transcriptional activity directly by inhibiting the binding of specific transcription factors, or indirectly by recruiting methyl-CpG-binding proteins. Conversely, DNA demethylation takes place passively via DNA replication, or actively via ten-eleven translocation (TET), forming the hydroxylated metabolite of 5mC (5hmC). By DNA methylation reprogramming, mammalian PGCs establish the monoallelic expression of imprinting genes, maintain inactivated retrotransposons, inactivate one of the two X chromosomes, and suppress gene expression.

Histones undergo post-translational modifications that reorganize their interactions with DNA and nuclear proteins. In particular, the tails of histones H3 and H4 can be covalently modified at specific residues. In terms of the regulation of gene expression, the processes that have been investigated most intensively are methylation and acetylation in histone H3. In addition to DNA methylation, histone post-translational modifications also specify the cellular features of PGCs.

Small non-coding RNAs do not produce proteins, but act as post-transcriptional regulators. An example of these RNAs is microRNAs (miRNAs), which are 18–23 nucleotides in length, bind to the complementary sequences of a target mRNA at the 3' untranslated region (UTR), and silence it through translational repression or mRNA degradation. Another category is piwi-interacting RNAs (piRNAs, 23–30 nucleotides), which are longer than miRNAs, are mainly derived from repetitive elements in the genome, and have a specific role in retrotransposon suppression through DNA methylation in the germline. In terms of post-transcriptional regulation, small RNAs including miRNAs and piRNAs are required to maintain PGCs and germline development in mouse, zebrafish, and fruit fly.

The epigenetic status of the germline is regulated by such mechanisms acting on the expression of genes that determine germ-cell-specific characteristics. The germline establishes an epigenetic signature to specify its cellular features and induce the abolition of somatic lineage differentiation during embryogenesis. In addition, changes in epigenetic marks are required for germline development, the regulation of meiosis, and genome integrity. Epigenetic dynamics is critical for early embryonic development, and for the germline,

throughout the animal kingdom. In roundworm, the activation of germline genes and suppression of somatic genes by histone modifications are crucial for germ cell development (Strome and Updike, 2015). Moreover, during early embryonic development in mammals, the germline, from specification to gametogenesis, exhibits unique epigenetic dynamics such as genome-wide demethylation, X-chromosome reactivation, histone modification, and transposon silencing (Sasaki and Matsui, 2008).

Epigenetic programming and reprogramming have been extensively studied in mammals because dramatic differences in epigenetic marks were observed between somatic lineages and PGCs. In addition, excellent models, such as a transgenic mouse model, have been developed based on reproductive technologies. Therefore, we have obtained a clear overview of epigenetics during germline development in mammals, in terms of DNA methylation, histone modification, and small RNAs. Generally, after specification, genome-wide epigenetic reprogramming occurs, such as global DNA demethylation for the erasure of imprinting and X-chromosome reactivation, and histone modification in the germline, regardless of the established epigenetic status of somatic cells. During this erasure, however, suppressive histone markers such as histone H3 lysine 9 trimethylation (H3K9me3) are maintained, inhibiting the somatic program, and the expression of retrotransposons and repeat elements in the germline (Tang et al., 2016). Subsequently, reconstitution of imprints is initiated by DNA remethylation during sexual differentiation. The piRNA pathway also plays a critical role in the differentiated male germline through *de novo* DNA methylation and retrotransposon suppression (Sasaki and Matsui, 2008). Moreover, next-generation sequencing technology enables investigation of the specific mechanisms by which epigenetic regulation acts on gene expression. However, few studies of epigenetics in non-mammalian species have been performed. Hereafter, we present findings on the epigenetic programming that characterizes the germline in non-mammalian vertebrates, including birds, reptiles, amphibians, and fish.

Epigenetic Programming of the Germline in Birds

Historically, birds have been a valuable animal model in a broad range of scientific fields. Especially in embryology and reproductive biology, because the avian embryo develops in an egg before hatching, it is an excellent *in vitro*-like *in vivo* system; this has given rise to substantial research on the developmental events that occur during embryogenesis. Birds also exhibit a unique characteristic during germline development compared to other species, namely, the migration of PGCs into blood vessels through the circulatory system until they settle in the genital ridge (Nieuwkoop and Sutasurya, 1979) (Fig. 1(A)). This feature enables the production of germline chimeras or transgenic birds via the injection of germline cells, specifically PGCs, into the blood vessels of the recipient embryo. Furthermore, in a representative model of avian species, chicken PGCs can be easily isolated from the blood or gonads of embryos, and cultured *in vitro* for a long period without losing their cellular character. These factors together make the avian germline be important not only for germ cell biology, but also for biotechnology.

Chicken PGCs were first described in the germinal crescent in terms of their distinct morphological aspects compared with those of somatic cells. The central region of the blastoderm can only give rise to PGCs, probably by an inductive signal, because there is no evidence of germ plasm during the early stages in aves. However, after the discovery and tracing of chicken VASA homolog (CVH), the origin of chicken PGCs in early development was firstly observed (Tsunekawa et al., 2000). VASA homologs are members of the ATP-dependent RNA helicase of the DEAD-box family that are highly conserved across species including mouse, frog, zebrafish, fruit fly, and roundworm. VASA is also well-known to be involved in germline specification following the preformation mode, and plays an essential role in germ cell development. The localization of CVH protein was granulofibrillar structures surrounding the mitochondrial cloud and spectrin protein-enriched structure in oocytes, indicating the evidence of germ plasm in birds. Furthermore, CVH was found in cleavage furrows and restricted to only six to eight cells in the 300-cell-stage embryo, suggesting that germ cell specification in chicken might be determined by maternally inherited determinants and follow the preformation mode. In addition, the expression and tracing of deleted in azoospermia-like (DAZL), which is another germline-specific RNA-binding protein, were used to investigate the origin of PGCs and germplasm dynamics during early development of chickens (Lee et al., 2016). DAZL has been well-studied in vertebrate species, in terms of meiotic progression and the maintenance of pluripotency in germ cells. Using chicken DAZL as a germ plasm marker, the germ granule was found to exhibit asymmetric localization in oocytes, and a change from a subcellular to a diffused form at which zygotic genome activation (ZGA) occurs during early cleavage. These studies indicated that the germ cells of avian species could be predetermined by maternally derived germ plasm (Fig. 1(A)). However, there is still a need for additional investigations, such as on the specific functions of germ plasm components and confirmation of these findings in other birds, to clarify definitively the mode of germline specification in birds.

Comprehensive analysis of epigenetic status during germline development has not been conducted in birds. However, recent studies revealed the epigenetic signature, including DNA methylation, histone modification, and post-transcriptional regulation by noncoding small RNAs, in chicken germline (Fig. 1(B)). During the migration of chicken germ cells, blood PGCs (E2.5) showed lower global 5mC than gonadal PGCs (E4.5 and E6.5), indicating that genome-wide DNA reprogramming occurs at this stage (Rengaraj et al., 2011). Moreover, differentially methylated regions, including seven hypomethylated and five hypermethylated ones, were found in chicken PGCs and exclusively matched the differential expression of genes compared with their levels in somatic cells. This provides insight into the role of DNA methylation in gene regulation in chicken PGCs. In addition, regions showing differential methylation between male and female PGCs were detected in chicken (Jang et al., 2013).

In addition to methylated regions of DNA, the nuclear distributions of histone modifications and methylated cytosine were observed. Most histone modifications and 5hmC were similar to those in mammalian cells, except for one repressive histone tail, H3K9me3. Chicken PGCs exhibited H3K9me3 for heterochromatin formation, instead of the trimethylation of histone H3

Fig. 1 Germline development (A) and epigenetic programming (B) in birds. (A) In chicken, germ plasm is expressed in germinal vesicles of oocytes. After the initiation of cell division at Eyal-giladi and Kochav stage I (EGK.I), germ plasm is localized in the cleavage furrow. During the formation of the primitive streak at Hamburger and Hamilton stage 4–5 (E1.0, HH4–5), primordial germ cells (PGCs) migrate to the germinal crescent. Subsequently, PGCs move into the bloodstream (E2.5, HH13–16) and migrate into the genital ridges (E3.5, HH18–21). Modified from Nieuwkoop, P.D., Sutasurya, L.A., 1979. *Primordial Germ Cells in the Chordates: Embryogenesis and Phylogenesis*. Cambridge University Press. (B) The reprogramming of DNA methylation in chicken PGCs seems to occur during migration. DNA methylation is also involved in germ cell-specific gene expression in chicken PGCs. Contrary to the findings for histone H3 lysine 27 tri-methylation (H3K27me3) in mammalian PGCs, histone H3 lysine 9 trimethylation (H3K9me3) is predominantly localized in heterochromatin in chicken PGCs. A chicken PGC-specific microRNA (miRNA), miR-181a-3p, has the dual functions of suppressing meiosis and somatic differentiation. Piwi-interacting RNAs (piRNAs) are also crucial small RNAs for PGC integrity.

on lysine 27 (H3K27me3) by polycomb group protein, as exhibited in mouse PGCs. This demonstrates that the avian-specific constitution of chromatin could differ from its epigenetic status in mammals (Kress *et al.*, 2016).

In the chicken germline, small RNAs have been shown to play very important roles, as revealed by the following studies. For example, after chicken PGC-specific miRNAs had been selected by a high-throughput microarray, miR-181a-3p was shown to have dual functions, namely, inhibition of somatic differentiation and prevention of meiotic progression, for the maintenance of undifferentiated characteristics of chicken PGCs. miR-181a-3p achieved this by suppressing the expression of genes related to the somatic lineage: homeobox A1, and a meiotic marker, nuclear receptor subfamily 6, group A, member 1 (Lee *et al.*, 2011). In addition to miRNAs, an abundance of germ-cell-specific small RNAs, piRNAs, which are derived from repetitive element sequences or protein-coding genes, was found in chicken PGCs using small RNA-seq. As in other species, piRNAs and piRNA pathway genes are required for the integrity of chicken PGCs (Rengaraj *et al.*, 2014). However, there is still a need for comprehensive research on epigenetic regulation in avian germline cells. In the future, the specific roles of epigenetic marks in the avian germline should be elucidated, by applying combined approaches including the use of the latest next-generation sequencing technology.

Epigenetic Programming of the Germline in Reptiles

In reptilian species, although there is still controversy about how PGC specification occurs, reptiles are believed to follow an inductive (epigenesis) mode, as also employed by mammals. Among reptiles, the germ plasm is considered to be absent in turtles, since *Dazl* and *Vasa* mRNAs were not detected in mature oocytes and PGCs were identified only after the early somite stage in turtle embryos (Bachvarova *et al.*, 2009); this indicates that an inductive mode of specification is employed in reptilian PGCs.

During the germline development of reptilian species, temperature-dependent sex determination is one of the major developmental events, which occurs by temperature-mediated epigenetic regulation. Since the expression of aromatase, *cytochrome P450 family 19 subfamily A member 1* (*cyp19a1*) gene, which is involved in the conversion of androgen into estrogen for female differentiation, is regulated in a temperature-dependent manner, DNA methylation of *cyp19a1* gene promoter is considered to be regulated by a temperature-induced DNMT or a temperature-induced signaling pathway (Navarro-Martin *et al.*, 2011). It is also found that upstream CpG islands near the gonad-specific TATA box are differently methylated during the period of temperature-dependent sex determination. In red-eared slider turtles, it is suggested that female-specific DNA hypomethylation and H3K4me3 modification in the promoter region of the *cyp19a1* aromatase gene are among the epigenetic regulatory mechanisms underlying sex determination in turtles in response to both temperature and genetic cues, allowing for the release of a transcriptional blockade, thus initiating a cascade resulting in ovarian differentiation (Matsumoto *et al.*, 2016).

Furthermore, a study conducted on sea turtles revealed a DNA methylation pattern that was sexually dimorphic between ovaries and testes. This depended on the incubation temperature, as the occurrence of DNA methylation or demethylation is temperature-dependent, since a difference in the DNA methylation signal has been correlated to the period of temperature-sensitive sex determination (Venegas *et al.*, 2016). More recently, in a study of bearded dragons, it was reported that temperature-induced sex-reversed female dragons preferentially retained an intron in the mature transcript of a jumonji chromatin modifier, *jumonji and AT-rich interaction domain containing 2* (*jarid2*) and *jumonji domain containing 3* (*jmjd3*) genes, which was not detected in normal female or male (Deveson *et al.*, 2017). This suggests that intron retention in *jarid2/jmjd3* can induce silencing and perturb the function of chromatin modifier genes, indicating that the epigenetic status of sex-reversed female changes dramatically compared with that of male, providing support for sex reversal and reptile temperature-dependent sex determination. These findings together suggest that DNA methylation events could drive differentiation of the bi-potential gonads of reptilian species into the male or female germline.

Epigenetic Programming of the Germline in Amphibians

Amphibian species are commonly used as vertebrate model systems for studying embryonic development, cell cycle, cancer and epigenetic mechanisms including miRNA function and chromatin structure. In particular, since the frog germline is established by localization of the maternally inherited components to the vegetal cytoplasm, called the germ plasm, studies on the molecular networks determining the germline have been intensively performed (Houston and King, 2000) (Fig. 2(A)).

In vertebrates, chromatin assembly mediated by histone modification and subsequent transcriptional regulation are critical steps for embryogenesis, as well as germline establishment, by regulating gene expression. However, in amphibian species, especially in frog PGCs, the histone modifications producing the chromatin structure are unlikely to involve germness-related gene expression. Previous research reported that there is no difference in histone modification between PGCs and somatic cells isolated from embryos at the maternal-to-zygotic transition stage. Instead, the suppression of zygotic gene expression of frog PGCs is due to the blocking of RNA polymerase II (RNAPII) activity by the failure to phosphorylate serine 2 in the carboxy-terminal domain (CTD) of the large subunit of RNAPII (Venkatarama *et al.*, 2010) (Fig. 2(B)).

Maintaining the germline characteristics, epigenetic regulation in the germline is also conserved in amphibian species. Indeed, large populations of mRNAs were already shown to be present in frog oocytes and fertilized eggs, and have been considered to play pivotal roles in embryonic development. In particular, miRNA-427, zebrafish ortholog miR-430, is abundant in early embryos and plays a role in maternal mRNA clearance. In contrast, the low expression of miR-427 in frog PGCs impedes efficient degradation of DEADSouth mRNA, which is localized in the germ plasm of fertilized eggs and encodes DEAD-box helicase 25 (DDX25), resulting in the maintenance of germness (Yamaguchi *et al.*, 2014). Similar to miR-427, miR-18 degrades *dnd1* mRNA in somatic cells, but not in the germline, indicating its regulatory roles in the expression of germness-related genes (Koebernick *et al.*, 2010) (Fig. 2(B)).

Besides the findings for miRNAs, translational regulation of small RNAs, including piRNAs, has been suggested in frog oocytes. High-throughput analysis of the frog female germline revealed that a number of small RNAs were specifically expressed in the female germline (Armisen *et al.*, 2009). Collectively, studies of the epigenetic programs in amphibian germlines showed their conserved roles and distinctive features in amphibian species compared with those in other species.

Epigenetic Programming of the Germline in Fish

During the first steps of embryo development, the parental somatic marks are completely erased in fish, like in other animal species. Subsequently, epigenetic marks are newly acquired in gametogenesis, allowing proper embryonic development. In mice, the PGCs migrating towards the embryonic genital ridge undergo a genome-wide erasure of methylation, which is known as the epigenetic ground stage (Sasaki and Matsui, 2008). However, the PGCs of fish arise from a few cells located in a matrix of mRNAs and proteins

Fig. 2 Germline development and epigenetic programming in amphibians. (A) In frog, germ plasm is initially deposited in the oocytes. During the cleavage stages, germ plasm accumulates at the vegetal pole (2-cell). In the blastula stage, germ plasm still remains in the vegetal blastomeres. During gastrulation, germ plasm moves to the posterior endoderm, and PGCs leave the endoderm and migrate to the dorsal body wall through dorsal mesentery (Stage 25–44). Modified from Houston, D.W., King, M.L., 2000. Germ plasm and molecular determinants of germ cell fate. *Curr Top Dev Biol* 50, 155–181. (B) During epigenetic programming in frog PGCs, zygotic gene expression is suppressed by inactive RNA polymerase II (RNAPII) through blocking the phosphorylation of serine 2 in the carboxy-terminal domain (CTD). miR-427 and miR-18 are highly expressed in somatic cells and inhibit germline development. piRNAs in frog are also expressed exclusively in PGCs.

in oocytes, called the germ plasm (Raz, 2003). Because this event occurs much earlier than embryo development, whether there is any process for the erasure/rewriting of epigenetic events in fish, similar to that in gametogenesis in mammals, has not been elucidated. Fish PGCs are formed in the germ plasm where maternal mRNAs and proteins required for PGC specification, such as *vasa*, *nanos*, and *dnd*, are concentrated (Raz, 2003) (Fig. 3(A)). After specification, PGCs migrate to the embryonic gonad and differentiate into functional gametes.

Compared with PGCs, the epigenome of mature male gametes of fish has been relatively well studied, especially in terms of DNA methylation and histone marks. Promoter regions of genes related on developmental regulators, transcription factors and metabolism are hypo-methylated (Wu *et al.*, 2011), although highly methylated CpGs (over 90%) were found in zebrafish sperm (Potok *et al.*, 2013; Jiang *et al.*, 2013). Moderate enrichment of active histone marks, including histone H3 lysine 4 trimethylation (H3K4me3), H3K4me2, and histone H4 lysine 16 acetylation (H4K16ac), occurs in developmental loci, whereas they are prominently found in genes related to meiosis and spermatogenesis (Wu *et al.*, 2011) (Fig. 3(B)).

Female gametogenesis showed a different profile from that in the male germline. The nuclear DNA of fish oocytes is less methylated than that of sperm (Potok *et al.*, 2013). Also, during ZGA in sphere stage, it has a tendency to be hypomethylated in differentially methylated regions (DMRs) in oocyte related to germline and early development related genes, but hypermethylated in DMRs in sperm, related to later functions of embryo development (Potok *et al.*, 2013) (Fig. 3(B)). The *Piwi* homologs, *Ziwi* and *Zili*, were also found in zebrafish (Houwing *et al.*, 2007). In fish, piRNAs are prominently found in both testes and ovaries where *Ziwi* is expressed, and may be associated with the silencing of transposons in the zebrafish germline (Houwing *et al.*, 2007).

Future Perspectives of Epigenetic Programming

Pioneering studies have provided a solid foundation for work on germline origin and development throughout the vertebrate species. However, the molecular mechanisms that define the germline should be characterized in detail. Epigenetic programming is the main focus with respect to how gene regulation influences germline cells. From the perspective of developmental and evolutionary biology, epigenetic regulation of the germline is highly conserved across the animal kingdom. Studies reported to date have

Fig. 3 Germline development and epigenetic programming in fish. (A) In zebrafish, germ plasm is first located in the oocytes. After fertilization, germ plasm is found in the cleavage planes (2-cell) and subsequently condensed into four clumps during 4-cell stage. These four clumps give rise to four PGC clusters (Dome). Then, PGCs migrate and accumulate in the region of the future gonad at 24 h post-fertilization. (24 hpf). Modified from Raz, E., 2003. Primordial germ-cell development: The zebrafish perspective. *Nat Rev Genet* 4, 690–700. (B) During epigenetic programming in zebrafish sperm and oocytes, sperm express the genes related to meiosis and spermatogenesis through active histone modifications. Differentially methylated regions (DMRs) involved in germline and early development in oocytes are going to be hypomethylated in sphere during ZGA.

indicated that there is an evolutionarily conserved regulatory mechanism involved in epigenetic programming in various vertebrates, including mammals, birds, reptilians, amphibians, and fish. Although core regulatory networks of epigenetic programs among vertebrates have been elucidated, there are also species-specific regulatory mechanisms that govern epigenetic regulation in response to their status and cellular environment. However, the specific mechanisms underlying the effects of each epigenetic mark are not fully understood, especially in non-mammalian species. Due to recent progress in genetic modification and genome editing technology using third-generation DNA scissors, clustered regularly interspaced short palindromic repeats (CRISPR)-associated (CRISPR/Cas9), there are now tools available for the genome editing of regions related to germline development, enabling the efficient production of model animals for germ cell research. This can be combined with reproductive technologies, such as those exploiting PGCs in birds and fish, as well as *in vitro* maturation and fertilization of embryos in amphibians. In addition, the advanced next-generation sequencing technologies facilitate epigenetic characterization via amplification of a small number of cells. Through these approaches, we can comprehensively monitor epigenetic dynamics from very small amounts of material from the early germline, such as PGCs, and even perform comparisons among single germline cells in individuals. These state-of-the-art techniques should provide us with a comprehensive understanding of epigenetic programming in the non-mammalian germline, and also contribute to fundamental research on epigenetics and the use of germ cells as genetic resources.

Nomenclature

AMH Anti-muellerian hormone

Amhy Anti-muellerian hormone on Y-chromosome

amhr2 Anti-muellerian hormone receptor type 2

amhr2-Y Anti-muellerian hormone receptor type 2 on Y-chromosome

Cbx2 Chromobox homolog 2

DGCR8 DiGeorges critical region 8 (double-cysteine-ligated heme protein)

DMRT1 Doublesex and mab-3 related transcription factor 1

ESD Environmental sex determination; when the sex of an individual is triggered by various external factors (*i.e.* temperature, PH, social interactions)

GSD Genetic sex determination; when the sex of an individual is triggered by its genotype only, including both mono or polygenic sex determination.

gsdf Gonadal soma-derived factor

gsdf-Y Gonadal soma-derived factor on Y-chromosome

HINTW Histidine triad binding protein, W-linked

HINTZ Histidine triad binding protein, Z-linked

HMG-box High mobility group DNA binding domain

nr5a1 Nuclear receptor 5a1 gene encoding the steroidogenic factor-1 (SF1)

rspo1 R-spondin 1

SD Sex determination system

sdY Sexual dimorphic on Y-chromosome (master sex-determining gene of salmonids)

Sox SRY-related HMG-box

sox3-Y SRY-related HMG-box factor 2 on Y-chromosome

SRY Sex determining region Y

TGF- β Transforming growth factor β (beta)

Wnt4 Wnt family member 4

XY System with X and Y sex chromosomes, females are XX (homogametic) and males XY (heterogametic)

ZZ/ZW System with Z and W sex chromosomes, males are ZZ (homogametic) and females WZ (heterogametic)

Mammals: RY all over since – and Forever?

Mammals are characterized by X and Y heteromorphic sex chromosomes (XY system). First discovered in the early 1990s the SRY gene (Koopman *et al.*, 1991) on the Y-chromosome in the sex-determining region has been shown to be the universal male master regulator. It initiates testis development in the bipotential gonad of most therian mammals (Waters *et al.*, 2007) (Fig. 1), with only a handful of exceptions known so far. In mice loss- and gain-of-function studies demonstrated that SRY is both necessary and sufficient for triggering testis development (Koopman *et al.*, 1991; Lovell-Badge and Robertson, 1990). In human, mutations of SRY lead to partial or complete gonadal dysgenesis, sex reversal or even in rare cases to hermaphroditism.

SRY acts as transcription factor. It has a single evolutionary conserved high mobility group DNA binding domain (HMG-box) which is flanked by more variable N- and C- terminal sequences. Being the prototype member of the SRY-box (Sox) gene family, SRY shares its protein architecture with other Sox factors. These include Sox3, Sox9 –a downstream target of SRY- and Sox10. These are able to substitute for SRY-driven activation of the male gonadal gene regulatory network when temporarily and topologically correctly expressed. Thus other Sox genes could, in principle, activate the male gonadal gene regulatory network. Intriguingly, the X-chromosomal Sox3-encoded protein is the Sox factor most similar to Sry (Stevanović *et al.*, 1993) sharing an overall amino acid identity of 67%, and up to 90% in the DNA binding domain (Table 1). Evolutionary studies integrating comparative molecular and cytogenetic data of mammalian sex chromosomes provided evidence that Sox3 is the likely ancestor of Sry. Sry most probably arose before the divergence of the therian lineage around 146–166 million years ago. The current model proposes that the proto-Y emerged after (i) a dominant mutation in the Y SOX3 allele attributed a new function and (ii) a consecutive

Fig. 1 Diversity and evolution of sex determination systems and master sex-determining genes in vertebrates. In contrast to therian mammals and birds, the other vertebrate groups including reptiles, amphibians and fish, exhibit plasticity of sex determination mechanisms (XX/XY, multiple X or Y, ZZ/ZW, multiple Z or W, autosomal modifiers and environmentally induced sex determination) and of master sex-determining genes.

Table 1 Diversity of sex determination systems in vertebrates

Organism	Master sex-determining gene	Sex-determination system	Sex-determining gene ancestor	Establishment
Therian mammals	SRY	XY	SOX3	Allelic Diversification
Birds	DMRT1	ZW	<i>Dmrt1</i>	Allelic Diversification
African clawed frog (<i>Xenopus laevis</i>)	<i>DM-W</i>	ZW	<i>dmrt1</i>	Gene Duplication
Medaka (<i>Oryzias latipes</i>)	<i>dmrt1bY</i>	XY	<i>dmrt1</i>	Gene Duplication
Luzon rice fish (<i>Oryzias luzonensis</i>)	<i>gsdf-Y</i>	XY	<i>gsdf</i>	Allelic diversification
Indian rice fish (<i>Oryzias dancena</i>)	<i>sox3-Y</i>	XY	<i>sox3</i>	Allelic Diversification
Rainbow trout (<i>Oncorhynchus mykiss</i>)	<i>sdY</i>	XY	<i>irf9</i>	Gene Duplication
Nile tilapia <i>Oreochromis niloticus</i>	<i>amhY</i>	XY	<i>amh</i>	Gene Duplication
Pejerrey (<i>Odontesthes hatcheri</i>)	<i>amhY</i>	XY	<i>amh</i>	Gene Duplication
Torafugu (<i>Takifugu rubripes</i>)	<i>amhr2-Y</i>	XY	<i>amhR2</i>	Allelic Diversification
Chinese tongue sole (<i>Cynoglossus semilaevis</i>)	<i>dmrt1</i>	ZW	<i>dmrt1</i>	Allelic Diversification
Sablefish (<i>Anoplopoma fimbria</i>)	<i>gsdf-Y</i>	XY	<i>gsdf</i>	Allelic Diversification
Turquoise Killifish (<i>Nothobranchius furzeri</i>)	<i>gdf6-Y</i>	XY	<i>gdf6</i>	Allelic Diversification

translocation-fusion-insertion of the mutated allele together with another gene (DGCR8) located on the X-chromosome (Sato et al., 2010) provided a novel expression pattern. The effective -though low- SOX3 mRNA levels in primordial gonads of frogs, fishes, chicken and mice together with the fact that overexpression of SOX3 leads to XX female to male sex reversal gene in mice and humans (Sutton et al., 2011) are consistent with this evolutionary theory. On the other hand, absence of SOX3 expression in

the developing gonads of marsupials (Pask *et al.*, 2000) and of any gonadal phenotype after loss-of-function mutations in mice and humans (Weiss *et al.*, 2003; Raverot *et al.*, 2005) nourished doubts about a comprehensive conserved role of SOX3.

Monotremes, Marsupials and the Origin of SRY

Studies on chromosome evolution in marsupials and monotremes provided important insight into the ancestral sex determination (SD) system of mammals around 180 million years ago, prior to the divergence of the therian mammals (Wallis *et al.*, 2008). Marsupials have a typical XY system, while monotremes display multiple different X and Y sex chromosomes (Fig. 1), which form a chain during meiosis.

Genes from the canonical SD pathway (*NR5A1*, *SOX9*, *RSPO1* or *WNT4*...) that were mapped on the platypus genome revealed that they are all located on autosomes (Grafodatskaya *et al.*, 2007); excluding them as legitimate candidates for master sex determining genes. Interestingly, *DMRT1*, the prime candidate sex determining gene in birds and the avowed master sex determining factor in several frog and fish species (Table 1 and Fig. 1), is located on X-chromosome #5 (El-Mogharbel *et al.*, 2007). This is intriguing, but means that it is present in two copies in females and only one in male. But all what we know so far about *DMRT1*, from human patients with haploinsufficiency of this gene and from sex determination in birds and several fish, is that double dosage is connected to male development, not female. Currently, the most promising candidate gene, identified by transcriptome analyses, encodes the anti-muellerian hormone (*AMH*). Further, its position within an ancient bloc of genes on Y-chromosome #5 is consistent with a function as sex-determining gene (Cortez *et al.*, 2014). Validation of this candidate awaits, however, functional characterization.

Marsupials, despite an apparently simpler genetic condition (XY system), with X-chromosomes homologous to a large part (more than 2/3rd) of the eutherian X-chromosomes and the *SRY* gene present on the Y-chromosome, display, however, major differences in sex differentiation compared to eutherians. Karyotyping of intersex marsupials revealed that a pouch-mammary/scrotum switch gene resides on the X-chromosome (Sharman *et al.*, 1970), pinpointing major genetic rewiring of the complete sex determining gene regulatory network between marsupials and eutherian mammals despite employing the same master sex determiner.

XY and XX Sex Reversals in Mammals: What's Next Beyond SRY?

In spite of proven robustness and apparent stability, the mammalian system involving heteromorphic XX/XY sex chromosomes and headed by *SRY* is nevertheless not totally locked and refractory to change. A handful of species – all rodents so far – have independently evolved viable alternative systems bypassing or surpassing *SRY* without significantly affecting their fertility (Table 2).

XY sex reversed mammals: Sry on the loose in evolution? XY sex-reversals have been reported in several mammalian species including: (i) the wood and arctic lemmings *Myopus schisticolor* and *Dicrostonyx torquatus*, respectively, (ii) nine species of the South American field mice of the genus *Akodon*, (iii) the African pygmy mouse *Mus minutoides* and (iv) Cabrera's vole *Microtus cabreræ*. Molecular and histological analyses confirmed the complete XY sex-reversed phenotypes. Cabrera's vole is so far the only mammalian species harboring non-functional copies of *Sry* on its X-chromosome. Although each time independently acquired, an evolutionary convergence underlies the genetics of XY sex reversals in all species. As common mechanism, the presence of a third sex chromosome, named *X**, which is derived from the X-chromosome, prevents the initiation of the Y-chromosome-driven male-specific program (Table 2). Thus three types of females are generated (XX, *XX**, *X*Y*) while males are "regular" XY. In essence this system behaves like a polygenic variation of the canonical mammalian scheme with segregation of two sex determining genes: *Sry* on the Y-chromosome and a dominant female determiner on the *X**-chromosome, which overrides *Sry* (see Parma *et al.* (2016) for review).

XX sex reversed mammals: Sry lost, who's next? Intriguingly, even SD systems without *SRY* on the Y or no Y-chromosome exist. As far as known this is still restricted to only four species of mole voles *Ellobius* (*tancrei*, *talpinus* and *alaicus*) and the spiny rats *Tokudaia*

Table 2 Alternative sex determination systems in therian mammals

Sex reversal	Species	Sex chromosomes	
		Female	Male
Female with Y-chromosome	Wood lemming (<i>Myopus schisticolor</i>)	XX, <i>XX*</i> , <i>X*Y</i>	XY
	Arctic lemming (<i>Dicrostonyx torquatus</i>)		
	South American field mice <i>Akodon</i> sp		
	African pygmy mouse (<i>Mus minutoides</i>)		
Male in absence of Y-chromosome	Mole voles (<i>Ellobius tancrei</i> ; <i>E. talpinus</i> ; <i>E. alaicus</i>)	XX	XX
	Mole vole (<i>Ellobius lutescens</i>)	X0	X0
	Spiny rats <i>Tokudaia</i> sp		

osimensis and *T. tokunoshimensis*. Lacking the complete Y-chromosome including *Sry*, both males and females are all XX or XO depending of the species (see [Table 2](#)). Although different hypothesis were followed up (Y-linked gene translocation, gene dosage of the *Cbx2* gene, segregating allelic variants...) the “new” testis determining factor of these species still remains to be identified (see [Parma et al. \(2016\)](#) for review).

The remarkable robustness of the mammalian system, headed by *SRY* on the Y-chromosome, has been explained by the propensity of sex chromosomes to hijack and selectively accumulate genes beneficial for the reproductive fitness of that sex once it was established ([Graves, 1995](#)). Indeed the mammalian Y-chromosome carries several genes involved in spermatogenesis. The more its specialization was reinforced the more its transmission in males became necessary and made it indispensable. Nevertheless, the examples from the “sex-reversed” mammalian species show that either ovarian or testis development with or without *Sry* (down to the complete absence of the Y-chromosome), respectively, are possible and viable.

Excitingly, much more than peculiar outliers, such „exceptions“ certainly represent invaluable cases of evolution in action. Hence, to challenge our hypotheses it will be interesting to find out what has happened to the male beneficial genes. Did they leave the Y-chromosome first and reside now elsewhere in the genome – thus making the Y vulnerable to full decay or loss? If they did leave, do they support, and to which degree, the emergence of a new sex determiner and sex chromosome in the vicinity of their new location?

Birds: DMRT1 all over since and forever?

Dmrt1 is a Dosage Sensitive Male Determiner on the Z-Chromosome

Akin to mammals, birds also evolved a stable pan-order system for determining sex ([Table 1](#) and [Fig. 1](#)). The ZZ/ZW female heterogametic sex chromosomes of birds are unrelated to those of mammals, and lack any homologue to the mammalian *Sry* gene.

Theoretically, for a female heterogametic system, three different mechanisms of SD can be considered: (i) a dominant female determiner located on the W-chromosome, (ii) Z-chromosome dosage of a male determining factor (2 copies in males, ZZ, and only one in females, ZW), or (iii) a combination of both eventually with different “strength” of the respective factors. Currently, although the fine-tuning of the mechanism(s) of avian SD remains to be resolved, the almost complete absence of Z-chromosome inactivation in birds favors a Z-dosage mechanism of a male determining factor. In that respect, *DMRT1* is the prime candidate. It is present on the Z but not on the W-chromosome in all birds including ratites (flightless emu, ostrich...) ([Nanda et al., 2002, 2008](#)). In chicken embryos *DMRT1* is always higher expressed in ZZ male primordial gonads. Once initiated above a certain threshold (two copies in ZZ *versus* one in ZW), a positive feedback loop amplifies *DMRT1* expression in ZZ gonads. Overexpression in female (ZW) primordial gonads drives male development, while suppression of gonadal *DMRT1* expression in males (ZZ) leads to feminization and sex reversal to female ([Smith et al., 2009](#)).

In summary, all evidence is compatible with *DMRT1* being the Z-linked dosage sensitive male determiner. Although less well studied than mammals for their master sex regulator, thus far no exception for such a mechanism has been reported from a bird species. Interestingly the *DMRT1* family of transcription factors is involved in SD or sexual development of a wide range of organisms from flies, worms, and corals to fish, frogs, birds and mammals.

The W Alternatives

In most avian Z- and W-chromosomes are highly heteromorphic. Similar to the X-chromosomes of mammals the chicken Z-chromosome displays a notable bias of sex-related genes. And, analogous to the mammalian Y, the chicken W-chromosome is basically the degraded counterpart of the Z-chromosome with only a handful of intact genes. Interestingly, in the W-specific region the *HINTW* gene is present in multiple copies and appears to have been subjected to positive selection ([Smith, 2007](#)). Being a truncated counterpart of the Z-linked *HINTZ* gene, its gene product might act as a dominant negative version, blocking a possible testis function of *HINTZ*. However, mis-expressing *HINTW* did not disturb male gonadal development. Further functional characterization of another W-linked candidate, *FET1* (female expressed transcript 1) was not more fruitful. Sequencing of the chicken W revealed 28 intact genes, but none of these was expressed exclusively in female-specific tissues ([Hirst et al., 2017](#)). This certainly does not close the book of a female determiner on the W, but - in conclusion - the counter-evidence is accumulating.

Reptiles: Exploiting all Systems

In contrast to mammals and birds with their relatively stable genetic systems, reptiles exhibit a continuum of SD ranging from male or female heterogamety (XX/XY and ZZ/ZW respectively) up to environmental mechanisms (mainly temperature sensitivity), where even closely related species can be different ([Fig. 1](#)). It has been suggested that temperature sensitivity is the ancient mechanism and sex chromosomes are derived, but this is not supported when sex-determining systems are plotted on the phylogenetic tree of reptiles ([Smith, 2007](#)). To date no gene that acts as master regulator in a sex chromosomal system has been identified in reptiles.

Systematic identification of cryptic sex chromosomes in some families of lizards and turtles revealed that changes between XX/XY, ZZ/ZW and temperature SD systems are common, suggesting frequent transitions ([Gamble et al., 2015](#)). The homomorphic, and molecularly lowly differentiated sex chromosomes in the vast majority of reptiles may not impose high evolutionary constraints for

transitions. But notably, even species with highly differentiated sex chromosomes (XX/XY or ZZ/ZW) are still exposed to temperature induced sex reversion. In some species of bearded dragons high temperatures cause ZZ male-to-female sex reversion, producing fertile females. Thus, constant high temperatures result in the total elimination of the W-chromosome within few generations. An analogous situation has been observed in the Eastern three-line skink where low temperatures induce sex reversal of XX females to males. In both cases the unidirectional sex reversal of only the homogametic, eliminates the disadvantage of producing possibly lethal or inferior WW or YY offspring and favours the emergence of a new system (Holleley *et al.*, 2016).

Amphibians: Transitions in Action

Amphibians appear to employ mainly GSD and all possible mechanisms (XY, ZW, multiple sex chromosomes, X0, W0) are reported based on cytogenetic findings (Fig. 1). The reports of environmental influence on SD all seem to be laboratory-borne and have no counterpart in nature. So far the genes triggering sexual development are known only in one frog species, and suspected in a second; and in both cases it is again *dmrt1*.

While *DMRT1* acts as a Z-linked dosage-dependent male determiner in birds, surprisingly in the African clawed frog *Xenopus laevis* a duplicated copy, named DM-W, this time on the W-chromosome, appears to fulfil its function as a dominant female determiner (Gamble *et al.*, 2015). Lacking the dimerization domain, it is proposed to affect the transcriptional activation of *Dmrt1* through a dominant-negative action. Thus in female frogs *Dmrt1* cannot exert its male determining function. Rather than initiating female development, the mutant version of *dmrt1* on the W in fact suppresses male development (Fig. 2).

In another frog, *Rana temporaria* nascent Y-chromosomes carry different alleles of *dmrt1* and a large collection of population genetic data and family analyses point to this gene as the most likely candidate for being the male sex determiner (Rodrigues *et al.*, 2017).

A large body of literature explains – theoretically – the ins and outs of sex chromosome evolution and transitions among sex chromosome systems. Nevertheless the opportunities to observe such evolution in action are more than sparse. Interestingly, several examples from SD in amphibians might offer that perspective. In the Western clawed frog, *Xenopus tropicalis*, it was reported that, in addition to the long known W and Z chromosomes, the presence of another male determining chromosome, a Y-chromosome, is present in some stocks derived from natural populations. Further on, overriding the feminizing effect of even two Z-chromosomes in triploids, the Y is much stronger than the Z, while the Z can determine maleness only in the absence of the W.

The Japanese wrinkled frog, *Rana rugosa*, is peculiar because populations from the North of Japan have female heterogamy and heteromorphic sex chromosomes, while the populations from the rest of Japan and Korea are XY with homo- or heteromorphic sex chromosomes (Uno *et al.*, 2008). Thus opposite SD systems appear to coexist within the same species. However, the question whether this situation is already reflecting allopatric divergence towards the formation of two separate species is open.

Fish Sex Determination: Variations on the Theme

For the most basal group of vertebrates, the agnathans, several reports (Johnson *et al.*, 2017) suggest environmental SD in lampreys. From the chondrichthyans (cartilaginous fish) there are reports from several ray species for heteromorphic chromosomes either in males or females and even multiple sex chromosome (Cruz *et al.*, 2011) and a X0 system (de Souza Valentim *et al.*, 2013). For the basal chondrichthyan group of chimaeras several cases of male heterogamy are reported (Maddock and Schwartz, 1996). For none of these basal vertebrates there is any clue what the molecular triggers behind their sexual development are.

From the ancient fish, gars, sturgeons, and bichirs, solid evidence for their SD mechanism is missing, because none of the so far studied species exhibited cytogenetic clues for the presence of sex chromosomes. The same is true for the sarcopterygian fish, the coelacanth *Latimeria chalumnae* and *L. menadoensis*, and the six lungfish species.

In the so-called modern fish, the teleosts, the diversity of vertebrate SD systems is particularly obvious (Fig. 1). Here, within groups of closely related species a wide spectrum of different systems can be found (Table 1). Interestingly, among each type a multitude of mechanisms, how to initiate either male or female gonadal fates, have been documented. Moreover, numerous variants and even combinations of the different systems (GSD and ESD) are commonly observed. Environmental cues are as diverse as density, growth rates, social relationships, water quality (O₂ levels, pH), or even visual cues. Of these the most prevalent environmental signal –assumed to be the most primitive mechanism of SD in vertebrates– is temperature (see Baroiller *et al.* (2009) for review).

In teleost species the “operating” genetic sex determination (GSD) systems range from “classical” male or female heterogamy and multiple sex chromosome, to autosomal modifiers acting on the sex-determining gene, and finally to true polygenic systems (Moore and Roberts, 2013; Volff and Schartl, 2001; Devlin and Nagahama, 2002). The coexistence of two or more of such systems is not rare and has even been reported within the same genus. For instance, species with XY and ZW GSD are found in ricefish, Tilapia or sticklebacks or even within the same species like in some populations of cichlids or platyfish (Volff and Schartl, 2001).

Interestingly, such a high plasticity regarding the terms and conditions of fish SD is also noticeable when both GSD and ESD coexist and modulate each other. At different latitudes, populations of Atlantic silverside (*Menidia menidia*) – a fish that exhibits a temperature-influence on SD – compensate for differences in thermal environment and seasonality by adjusting the response of sex ratio to temperature through altering the level of environmental control over a basic genetic control (Conover and Heins, 1987). Laboratory strains of zebrafish cope with a weak genetic polyfactorial system (Anderson *et al.*, 2012) involving four different

Fig. 2 Mechanisms accounting for the emergence of new master sex-determining genes after either gene duplication (examples medaka and frog) or allelic diversification (examples torafugu, birds and tongue sole). (A) The medaka *dmrt1* gene, together with neighboring genes (including *dmrt2* and 3), first underwent local gene duplication. This whole duplicated segment was then inserted into another chromosome, creating a proto Y-chromosome. Because of non-homology of the insert to the proto-X recombination is suppressed and this part of the proto Y segment degenerated. Transposable elements and repetitive sequences accumulated, resulting in transcriptional rewiring of the *dmrt1bY* gene and acquisition of an early gonadal expression pattern compatible with a master sex-determining function. Further on, point mutations accounted for neo-functionalization and specialization of the *dmrt1bY* gene (Reproduced from: Herpin and Scharl, 2008. Regulatory putsches create new ways of determining sexual development. EMBO Rep. 9, 966–968; Herpin and Scharl, 2009. Molecular mechanisms of sex determination and evolution of the Y-chromosome: Insights from the medakafish (*Oryzias latipes*). Mol. Cell. Endocrinol. 306, 51–58. and Herpin et al., 2010. Transcriptional rewiring of the sex determining *dmrt1* gene duplicate by transposable elements. PLOS Genet. 6, e1000844.). (B) In the pufferfish as a result of allelic diversification two versions of the *amh* receptor II exist differing only by one amino acid located in the kinase domain (H384D). This hypomorphic mutation conferring lower receptor activity is encoded on the X-chromosome. Quantitative variations in *Amh* signaling in females (homozygous for the hypomorphic *amhrll* allele) versus males (heterozygous for the wild type and hypomorphic alleles), account for male gonadal development (Reproduced from Kamiya et al., 2012. A trans-species missense SNP in *Amh2* is associated with sex determination in the tiger pufferfish, *Takifugu rubripes* (fugu) PLOS Genet. 8, e1002798). (C) Birds and the tongue sole and have a ZW female heterogametic system. A single loss of function event in the *dmrt1* gene occurred (W allele). This resulted in ZW individuals having only one copy of the *dmrt1* gene while ZZ individuals harbour two copies (red stars indicate functional *dmrt1* genes). Here a dosage effect leads to either female (ZW, 1 “dose” of *dmrt1*) or male (ZZ, 2 “doses” of *dmrt1*) gonadal development respectively (Smith et al., 2009. The avian Z-linked gene *DMRT1* is required for male sex determination in the chicken Nature 461, 267–271; Chen et al., 2014. Whole-genome sequence of a flatfish provides insights into ZW sex chromosome evolution and adaptation to a benthic lifestyle Nat. Genet. 46, 253–260). (D) Sex determination in the frog *Xenopus laevis* is female heterogamety. Similar to medaka the frog *dmrt1* gene underwent gene duplication and translocation. Additionally truncation of the *dmrt1* gene occurred, generating a dominant negative version (DM-W). The DM-W protein product from the W-chromosome antagonizes the action of the wild type *dmrt1* gene on the Z-chromosome, leading to female gonadal development. ZZ individuals having two copies of the *dmrt1* gene (and no DM-W) develop as males (Yoshimoto et al., 2008). Red and blue stars indicate functional and dominant-negative version of the *dmrt1* gene respectively.

chromosomes (Dre 3, 4, 5, 16) and environmental modulators (hypoxia, high density, temperature, altered thermocycles, poor nutrition of even gamma rays,) for SD. Even in medaka, which has a strong Y-linked GSD, the system is still sensitive to thermal modulation: high temperature induces XX female to male sex reversal (Sato et al., 2005).

On the molecular level, different genes or pathways can be strong primary triggers (master sex-determining genes) for sexual development in fish (see Table 1 and (Herpin and Scharl, 2015)). The most classical ones, now referred as “usual suspects”, are genes that are derived from known actors of the sexual development regulatory network (Herpin and Scharl, 2015). First described in medaka (*Oryzias latipes*, XX/XY) *dmrt1bY* is probably the archetype of the transcription factor class of master sex determining genes (Table 1 and Fig. 2). This now also includes *dmrt1* in the Chinese tongue sole (*Cynoglossus semilaevis*, ZZ/ZW) (Table 1 and Fig. 2).

and *sox3-Y* in the Indian ricefish (*Oryzias dancena*, XX/XY). The other “usual suspects” come from the TGF- β signalling pathway (see **Table 1** and **Fig. 1**). The prototype members of this group are *amhy* and *amhr2-Y* in the Patagonian silverside (*Odontesthes hatcheri*) and the Japanese pufferfish (*Takifugu rubripes*) respectively (see **Table 1** and (Herpin and Schartl, 2015) for review). Other TGF- β factors that arose as SD triggers are *gsdf-Y* in the Luzon ricefish (*Oryzias luzonensis*) and the sablefish (*Anoplopoma fimbria*) derived from the fish specific gonadal soma derived factor gene, and *gdf6-Y* in the turquoise killifish (*Nothobranchius fuzeri*) (**Table 1** and **Fig. 1**). As exception so far, *sdY*, which is the master sex determining gene of rainbow trout (*Oncorhynchus mykiss*) and the whole salmonid family, has no homology to any known gene belonging to the SD pathways but is derived from an immune gene (*irf9*) (Yano *et al.*, 2012). The molecular mechanism(s) through which this “usurpator” triggers male gonadal development are still unknown.

An intriguing situation has been uncovered in the prejerrey, *Odontesthes bonariensis*, where sex is determined by temperature (Yamamoto *et al.*, 2014). Its congener *O. hatcheri*, has XY GSD with *amhy* as the dominant male determining gene on the Y. Surprisingly, the prejerrey also has *amhy*. At intermediate temperatures, which make about equal numbers of males and females, heterozygous presence of *amhy* determines males. At high and low temperature the action of *amhy* is overridden, but still may represent the interface between the environmental signal and the endogenous regulatory network.

The Commonality of Vertebrate Sex Determination: Evolutionary Principles for Variety

Generally speaking the development of the gonads in vertebrates is conceptually not different from other organs. During embryogenesis an uncommitted tissue is determined by a sequence of molecular events to become either a testis or an ovary. Once determined, differentiation genes establish the morphology and physiology of the respective organ. The preceding determination is initiated by expression of a master regulator that triggers a regulatory network, which finally activates the differentiation genes. The inherent program of the network is either to promote one sex or to prevent differentiation of the opposite sex or both.

The short survey in this article of the known SD mechanism and the genes which govern it already makes clear that SD in vertebrates is an evolutionary extremely plastic process – different from the majority of other developmental pathways, which display conservation of master regulators and effectors as well as their interaction. The non-conservation of the SD master regulators became obvious when *sry* was not detected outside mammals and was confirmed with the finding of *dmrt1bY* in medaka years later as a first instance of a non-Sry male determiner in vertebrates. Conversely, the major components of the downstream regulatory gene network governed by the different master genes were found in all species and led in conjunction with similar findings from flies and worms to the paradigm that “masters change, slaves remain”. More detailed studies revealed that the conservation of the members of the regulatory network is far from complete and that the genetic interactions and the resulting gene expression are also subject to change (Herpin *et al.*, 2013). An explanation for this extended plasticity is that the changes in the network are imposed by the change of the master SD gene. Most of the existing hypothesis of the evolutionary instability of SD systems in vertebrates aim at explaining the changes at the top and consequently would argue that the network changes are a consequence of emergence of a new genetic trigger for the system. These theories include the reasoning that any mutation, which creates a new sex determiner, will give a fitness advantage to its carrier if the new mutation is superior to the established mechanism. Over time this mutation will sweep through the population, and the previous SD gene disappears. The loss of the sex chromosome in several rodents and in the zebrafish laboratory strain supports another hypothesis, which posits that due to genetic degeneration or overriding external effects the heterogametic sex chromosome gets shed from the population and a new one with a new SD gene evolves from an autosome. The superiority of the new sex chromosome comes from its lower mutational load compared to the degenerated old one. Its establishment and persistence – at least for a while – is explained by one major theory that is based on linkage of the new SD gene to other genes that favor one sex and/or are detrimental to the other sex. The emerging SD gene, even when it is not a strong virtue to its carrier, benefits as a hitchhiker to the fitness advantage, which the sex beneficial or sex antagonistic gene in its vicinity brings with it. In any of these cases the new SD gene has to connect to a pre-existing genetic circuit and creating such an interface may also impact the conformation of further downstream interactions.

Besides these “top-down” explanations, which postulate positive selection for new SD genes there are also “bottom-up” (Wilkins, 1995) and “multi-hit” scenarios, which consider neutral or non-adaptive processes including random mutations, genetic drift and recombination as important drivers. Here the argument is that natural selection acts only on the final output of the SD process, namely the functionality of a testis and an ovary. As long as this is guaranteed changes of the upstream system can occur *ad libitum*. Those changes then can become fixed in a population by random genetic drift. This scenario allows the downstream SD network to vary in a similar or even more pronounced manner than the master SD genes.

The origin of the vertebrate SD genes basically follows two routes (**Table 1** and **Fig. 2**). (I) A duplication of a gene that is a member of the SD regulatory network (with the possible exception of *sdY* of salmonid fish) produces a second copy that is free to evolve, acquires some new features (neo-functionalization) and become the main trigger of the network. In all cases known so far this second copy was trans-located to another chromosome, which then became the Y or W. (II) Alternatively, allelic diversification at a locus leads to one of the alleles promoting either female or male SD. Again in vertebrates this happened as far as known at loci that are components of the regulatory network. In the ZW systems (birds, tongue sole) the non-sex promoting allele was non-functionalized and a dosage dependent male determiner, *dmrt1*, triggers testis development (**Fig. 2**). In the XY systems the allele on the proto-Y took over the new function, while it appears (although functional experimental evidence is missing) that the X-allele kept the ancestral function. In the allelic diversification cases the master SD genes did not change place in the genome.

How the environmental SD of fish and reptiles evolved and how SD works on the molecular level is barely understood, but there is accumulating evidence that the regulatory network is also in place. It is reasonable to assume that the environmental trigger, similar to a genetic trigger has an interface with the network, activating and/or deactivating the male or female program.

Glossary

Amh Anti-mullerian hormone.

Amhr2 Anti-Mullerian hormone receptor type 2.

Allelic diversification A process that starts from a step-wise diversification of two alleles of a sex chromosome pair. One allele then becomes the sex determiner, while the other allele either retains a non-SD function or favors the development of the opposite sex.

DMRT1 Doublesex and mab-3 related transcription factors.

Environmental sex determination (ESD) When the sex of an individual is triggered by various external factors (i.e. temperature, pH, social interaction).

Gdf6 Growth differentiation factor 6.

Genetic sex determination (GSD) When the sex of an individual is triggered by its genotype only, including both mono or polygenic sex determination.

Gonochorism A state of having just one of at least two distinct sexes in any one individual organism.

Gsdf Gonadal soma derived growth factor.

Haploinsufficiency When a diploid organism has lost one copy of a gene and is left with a single functional copy of that gene and this single copy does not produce enough product to display the wild type's phenotypic characteristics.

Homomorphic/heteromorphic sex chromosomes If the two sex chromosomes in a pair can be distinguished cytologically by their differences in morphology, they are termed heteromorphic sex chromosomes. If the two sex chromosomes are morphologically identical, they are called homomorphic sex chromosomes (the degree of differentiation is usually correlated with the age of the sex chromosome pair).

Irf9 Interferon related factor 9.

Master sex determination gene A gene responsible for triggering the embryo towards either male or female development. It is not necessarily that this gene codes for a protein.

Neofunctionalization A gene changes its function or acquires a new function by altering the structure of its gene product and/or its expression pattern.

PGC Primordial germ cells, which are the precursors of the stem cells that will give rise to the germ cell lineage.

Recombination The process of forming new allelic combination in offspring by exchanges between parental genetic materials.

Sex chromosomes Chromosomes that usually harbour a master sex determination gene and are involved in the primary genetic sex determination.

Sex determination (SD) Primary mechanism leading to the expression of the phenotypic sex.

SDY Sexual dimorphic on the Y chromosome (Salmonids).

SNP Single nucleotide polymorphism.

SOX Sry-related high mobility group box.

SRY Sex determining region Y.

TE Transposable element.

TGF- β Transforming growth factor beta.

Therian mammal Non-egg-laying mammals, including placental mammals and marsupials.

Sex Determination and Sex Chromosomes

Sexual reproduction is a widespread phenomenon, which requires two sexes in a population. There are multiple ways to achieve this state, but the most common in vertebrates is gonochorism, where individuals acquire their sex during development and maintain their sexual fate throughout life. This sexual identity is triggered by a process called sex determination (SD), in which a “master switch” controls a downstream regulatory cascade leading to either male or female gonadal development. In contrast with other more conserved developmental programs, SD master switches can be highly variable with primary signals coming either from the genome (genetic sex determination or GSD), or from the environment (environmental sex determination or ESD). Genetic sex determination involves sex chromosomes that harbor inherited master SD genes (not necessarily coding for a protein), responsible for the initiation of the SD process (Herpin and Schartl, 2015). One species can have one master SD gene (monofactorial system) or multiple SD genes (polygenic system). In a monofactorial system, one sex is heterogametic with two different sex

chromosomes; the other sex is homogametic with two of the same type of sex chromosome. A male heterogametic system is termed XX-XY system (i.e., like in most mammals), where the Y chromosome carries the male master SD gene; a female heterogametic system is denominated ZZ-ZW system (i.e., like in birds), where the W chromosome carries the female SD gene (Heule *et al.*, 2014). Contrarily to monofactorial systems, polygenic systems (Moore and Roberts, 2013) involve more than two alleles: either one locus with multiple independently segregating alleles, or multiple loci interacting through epistasis. However, such systems are more complex and less well documented than monofactorial systems. Unlike most mammals and birds where one type of monofactorial system has been conserved for over 100 millions years, fish display a high diversity of sex determination systems including various types of monofactorial and polygenic systems. Moreover, sex determination systems in fish can differ between very closely related species, sometimes even among different populations of the same species. Furthermore, in some species, genetic factors can interact with environmental cues (most commonly temperature), generating intricate sex determination mechanisms. Such evolutionary dynamics makes fish an attractive group to study the evolution of sex determination systems. It is worth noting that studies from other taxa, such as amphibians and reptiles, have also revealed a comparable degree of diversity in sex determination systems (Kikuchi and Hamaguchi, 2013); however, to date, fish has provided the most abundant knowledge on sex determination and its evolution in vertebrates. While fish is a more generic term that can include several taxonomic groups, so far all the identified master SD genes were found in teleost fish. For this reason, we will be focusing on the evolution of sex determination genes in this subgroup.

Fish Sex Determining Genes

The high diversity of sex determination systems seen in teleost fish is linked to the high turnover rate of their sex chromosomes. As a result, most fish sex chromosomes are considered to be relatively young and are often described as being homomorphic, i.e., with little differentiation and no cytological difference. Sex chromosomes turnover is usually connected with the emergence of new master SD genes. Indeed, in therian mammals and birds, master SD genes are highly conserved with the quasi-exclusive usage of *SRY* for mammals and *DMRT1* for birds. But, a high diversity of SD genes (Fig. 1) has been found in the past two decades in many teleost fish and this has greatly expanded our understanding of the SD mechanisms and SD evolution. Despite this great diversity, most of these newly discovered fish master SD genes are classical “usual suspects” (Herpin and Scharl, 2015) that fall into three independent protein families implicated in the “canonical” vertebrate sex differentiation gene network, namely the Sry-related HMG box (SOX), the Doublesex and mab-3 related transcription factors (DMRT) and the transforming growth factors (TGF- β) family. Their recruitments as master SD genes do not follow any obvious phylogenetic relationship and are more likely to be independent and repeated events during teleost evolution (Fig. 1). Only one known exception to this “usual suspects” rule is the salmonid SD gene, *sdY* (sex determining region on the Y chromosome), which was derived from the duplication of an immune-related gene unsuspected to be involved in the sex differentiation pathway.

The birth of a new master SD genes can start with a duplication of an autosomal gene that will acquire a new SD function leading to new sex chromosomes. On the other hand, it can begin with allelic diversification from a step-wise diversification of two alleles of the future sex chromosome pair. One allele then becomes the sex determiner, while the other allele either retains a non-SD function or favors the development of the opposite sex. (Kikuchi and Hamaguchi, 2013). The gene duplication and allelic diversification mechanisms have both been found in teleost fish to generate new master SD genes and drive the turnover of sex chromosomes (Table 1).

In the following part of this article, we will review the cases of master sex determination genes in teleost fish and the key publications on their discoveries can all be found in Table 1.

DMRT1: A Multi-Context SD Gene

The *dmrt1* gene is a transcriptional factor belonging to the evolutionarily well-conserved DM (Doublesex and Mad-3) domain DMRT gene family, which is involved in sexual development in many phylogenetically distant groups from worms to mammals. In teleost fish, sexually dimorphic expression of *dmrt1* has been correlated with gonadal identity in both gonochoristic and hermaphroditic fish species (Herpin and Scharl, 2011). *dmy/dmrt1bY*, was the first non-mammalian SD gene found in vertebrates and it is a duplicated copy of autosomal *dmrt1/dmrt1a* gene found in two ricefish species of the genus *Oryzias*: the Japanese medaka (*O. latipes*) and the Malabar ricefish (*O. curvinotus*), both having an XX/XY sex determination system. *dmy/dmrt1bY* arose about 5–10 million years ago from a local duplication of an autosomal fragment encompassing the *dmrt1* gene. Consequently, this pair of X and Y chromosomes are very young in comparison with the chromosome pair found in therian mammals, and remain homomorphic.

The expression pattern of the medaka *dmrt1bY* is typical of a master SD gene with an early and transient expression during gonadal primordium differentiation, and low persistence in the adult gonads. Around the time of hatching *dmy/dmrt1bY* is first expressed in the nuclei of the somatic undifferentiated cells surrounding the primordial germ cells (PGC) and later on exclusively in the sertoli cells in males. In comparison, the autosomal *dmrt1/dmrt1a* is expressed much later at 20 days after hatching in males and shows a testis-specific expression pattern in adult males with 50 times higher expression than that of *dmy/dmrt1bY*.

Concomitantly to the acquisition of a dominant position within the sex-determining network, *dmy/dmrt1bY* was subjected to a profound rearrangement of its regulatory landscape brought about by exaptation of a “ready-to-use” cis-regulatory element

Fig. 1 Evolution and diversity of sex-determining genes in vertebrates with a focus on teleost fish. Species with a known or highly suspected SD gene are mentioned in bold type at each tip of the tree leaves along with the name of the SD gene. A few other taxa in which no SD gene is currently reported are also represented in normal type with a question mark.

Table 1 Currently known or suspected master sex determining genes in fish. Not all master SD genes found in teleost species have been shown to fulfill all classical SD requirements. Confidence in their sex determining role and function is given in validation column. References to species-specific publications are given in the publication column with a link to the DOI of the publication

from a transposable element (TE). This element, called *Izanagi*, acts as a silencer to turn-off the *dmy/dmrt1bY* gene after it has fulfilled its male SD function (Herpin *et al.*, 2010).

In the medaka, the duplication/insertion of *dmrt1* led to a dominant *dmy/dmrt1bY* master SD on the Y chromosome, but interestingly *dmrt1* has also been found as the master SD gene in a fish species with ZZ/ZW sex determination system: the half-smooth tongue sole (*Cynoglossus semilaevis*). In this species *dmrt1* is only found on the Z chromosome while its homolog on the W chromosome is highly degenerated, probably a result of an old allelic diversification process. Even though homogametic sex is male in this species with two copies of Z chromosomes, SD operates through a Z-encoded mechanism that determines male development: the presence of two copies of *dmrt1* in ZZ animals leads to male development, while having only one functional copy (haploinsufficiency) in ZW individuals results in female development. *Dmrt1* is expressed specifically in male germ cells and pre-somatic cells of the undifferentiated gonad at the sex determination stage, fulfilling a key feature of male SD gene. Furthermore, functional knock-out of this gene resulted in male to female sex reversal, indicating its essential role of male SD gene in this species. The sex chromosome pair in tongue sole is thought to be around 30 millions years old, but whether closely related species of the tongue sole conserved *dmrt1* as a master SD gene is currently unknown. Interestingly, the sex chromosomes of the half-smooth tongue sole share the same ancestral vertebrate protochromosome as the W and Z chromosome in avians, which also have a Z dosage-dependent male sex determination system based on the *Dmrt1* gene, highlighting an evolutionary convergence around *Dmrt1*.

These two teleost cases show that *dmrt1* can acquire its position as a master SD gene through both allelic diversification and gene duplication mechanisms and its function as a SD gene can be triggered either by expression dosage effect or rewired transcription. Combined with its known SD roles in avians and some frogs (Yoshimoto *et al.*, 2008), *dmrt1* thus appears to be a highly versatile and flexible master SD gene.

Sox3 a Conserved Role in Vertebrate Sex Determination

SRY, the mammalian master SD gene on the Y chromosome is thought to be originated from an allelic diversification of the X-linked SOX3 gene. This is reminiscent of what has been found the Indian ricefish (*Oryzias latipes*), in which a novel sex chromosome recently evolved by co-option of this *Sox3* gene. In this species, the Y chromosome allele of *Sox3* (*Sox3^Y*) encodes the exact same amino-acid sequence as its X chromosome counterpart. However, a distant and specific *cis*-regulatory element of *Sox3* on the Y chromosome induces a gonadal specific expression of *Sox3* only in XY embryos, providing a SD signal in differentiating gonads. XX transgenic fish with the *Sox3^Y* regulatory segment developed as male and the loss of function mutation of *Sox3^Y* in XY fish lead to ovary-type gonads, supporting the SD role of *Sox3^Y* in that species. It was also demonstrated that the early testis specific expression of *Sox3^Y* initiates the expression of *gsdf*, a gene conserved in teleost testicular differentiation pathways, and induces testicular differentiation. However, the overexpression of *Sox3^Y* in the sister species *O. latipes* which has *dmy/dmrt1bY* as the master SD gene, could not induce testicular differentiation. This result indicates that co-evolved components in the downstream sex differentiation pathways are required for *Sox3^Y* to act as the master switch for male development (Herpin and Scharl, 2015).

The evolutionary parallel between *Sry* in therian mammals and *Sox3^Y* in Indian ricefish underlines the conserved importance of *sox3* in vertebrate sex determination.

The TGF- β Family: A SD Genes Jungle

A long-standing hypothesis, following the discovery of SRY in mammals, was that vertebrate SD genes should be transcription factors. The identification of *dmy/dmrt1bY* as the SD gene in *O. latipes* also supported this view. However, more recent evidences in teleosts have substantiated the idea that SD genes does not necessarily need to be transcriptional factors and members of the TGF- β family have emerged as master SD switches in teleost fish.

The first TGF- β related SD gene was identified in the Patagonian pejerrey (*Odontesthes hatcheri*). In this XX/XY species, a duplication of the anti-müllerian hormone (*amh*) was only found in males. *Amh* is a TGF- β hormone mainly known in mammals, birds and reptiles for its role in the regression of Müllerian ducts during male fetal development. Although teleosts lack the Müllerian ducts, they possess both *amh* and its type II receptor *amhr2* and this pathway has been implicated in the regulation of germ cell proliferation, spermatogenesis and regulation of gonadal sex-steroid synthesis. In the Patagonian pejerrey, this male-specific duplicated *amh*, called *amhy*, shares a high identity with its autosomal copy *amha* but has a Y-specific insertion in its third intron. Being very similar within the coding sequence to the autosomal *amha*, *amhy* is thought to fulfill its SD role through an earlier expression in the differentiating male gonads. This male-specific duplication of *amh* is also conserved in a closely sister species *O. bonariensis*, whose SD is known to be also modulated by temperature (Yamamoto *et al.*, 2014). In addition, in a more distant *Atheriniformes* species, a truncated duplicated copy of *amh* is suspected to be involved in male sex determination. However, due to greater sequence divergence, it has not been resolved whether this truncated duplicate of *amh* shares ancestry with the previous two cases or is an independent recruitment of the same SD gene. In the Nile tilapia (*Oreochromis niloticus*), a tandem duplication of *amh* has been found on the Y chromosome. This tandem duplication consists of a gene encoding a truncated protein lacking the TGF- β domain (*amh- Δ y*), and immediately downstream an *amhy* gene that is identical to the X-linked *amh* except for a single missense single nucleotide polymorphism (SNP). Both *amh- Δ y* and *amhy* are exclusively expressed in XY gonads during the onset of sex determination period in Nile tilapia. Similar expression profile of the X-linked *amh* and their receptor *amhr2* was found in both XX and XY gonads. However, only the knock-out of *amhy* lead to male to female sex reversal in XY individuals, while the knock-out of *amh- Δ y* alone had no effect. Additionally, overexpression of *amhy* caused female to male sex reversal in XX fish, but not the overexpression of the

X-linked *amh* or the truncated *amh-Δy*. Collectively, these results show that *amhy* is the master SD gene in Nile tilapia. More recently, another fish species, the lingcod (*Ophiodon elongatus*), has been characterized with a male-specific duplicate of *amh*. Although no expression nor functional data were available to consolidate its SD function, it potentially provides another independent case of recruitment of *amh* as a master SD gene in teleosts.

Interestingly the Amh type II specific receptor gene, *amhr2*, has also been identified as a SD gene in fish. In the pufferfish (*Takifugu rubripes*), a species with an XX/XY SD system, a missense SNP in the kinase domain of *amhr2* was found to be the only polymorphism strictly associated with phenotypic sex with males being heterozygous and females homozygous. Sex is then determined by the combination of these two X and Y *amhr2* alleles. This SNP leads to a single amino acid substitution and the X allele confers a decreased AMH signal transduction in XX females, while XY males with the wild-type *amhr2* Y allele would have a better Amh signaling, leading to testicular differentiation. This result is consistent with the mekade *hotei* mutant in which the impaired *amhr2* activity is linked with the feminization of the gonads. Surprisingly, this single missense SNP associated with male development is conserved over 10 million years of evolution, as it is present in two other Takifugu species (*T. pardalis* and *T. peocilonotus*).

The gonadal soma derived growth factor (*Gsdf*) is another vertebrate TGF- β ligand closely related to Bone Morphogenetic Proteins (BMPs), which has been lost in tetrapods. This *gsdf* gene was first characterized in rainbow trout as an inducer of germ cells proliferation, and has since been associated with testicular development due to its exclusive expression in the early differentiating testis of all teleosts examined so far (Herpin and Scharl, 2015). In *Oryzias luzonensis*, an XX-XY ricefish species closely related to the Japanese medaka *O. latipes*, X and Y alleles of *gsdf* have been identified, and *gsdf^Y*, the Y chromosome allelic form of *gsdf*, has been further characterized as a master SD gene. *gsdf^Y* and *gsdf^X* slightly differ in their sequence, but encode identical proteins. The testicular differentiation inducing role of *gsdf^Y* is triggered by a cis-regulatory region affecting a potential binding site for steroidogenic factor 1 (*sf1* or *nr5a1*) in the *gsdf^Y* promoter, conferring an elevated and earlier expression level of *gsdf^Y* during sexual differentiation than that of *gsdf^X* allele. Overexpression of the *gsdf^Y* locus in XX females is able to induce masculinization, corroborating its role as a male master SD gene in *O. luzonensis*. In addition, this overexpression of *gsdf^Y* is also able to induce masculinization of XX females in the sister species *O. latipes* which has *dmy/dmrt1bY* as the master SD gene, suggesting that *gsdf^Y* could functionally replace *dmy/dmrt1bY*. A few other fish species have been also described to rely on *gsdf* as a putative master SD gene, i.e., the sablefish, *Anaplopoma fimbria* and two rockfish species, *Sebastes carnatus* and *S. chrysomelas*.

Growth differentiation factor 6 (*Gdf6*) is a member of the TGF- β family known to be involved in vertebral segmentation and cell differentiation. While no gonadal function was reported previously for this gene, *gdf6Y* emerged recently as a putative SD gene in the turquoise killifish, *Nothobranchius furzeri*. In this species, the *gdf6* locus is sex-linked with specific X and Y chromosomal allelic variations that affect the Gdf6 protein function. So far, functional evidence of its role as a SD gene is not available, yet the Y chromosome allele, *gdf6Y*, exhibits a clear sex-linked expression during testicular differentiation, supporting its SD role in this species.

sdY: An Unusual and Conserved SD Gene in Salmonids

All of the above-described SD genes belong to the so-called ‘usual suspects’ category but the recent discovery of a new type of SD gene in rainbow trout (*Oncorhynchus mykiss*) demonstrated an unexpected flexibility in vertebrate SD. This gene, called *sdY*, came to the spotlight as it was found to be expressed only in embryonic testes and was also tightly linked to the sex-locus on the Y chromosome. It was further confirmed to be the trout SD gene based on functional proofs showing that *sdY* is by itself necessary and sufficient to induce testicular differentiation. One of the multiple unusual characteristics of *sdY* is that it evolved from the duplication of an immune related gene, *irf9* (interferon related factor 9) and compared to its ancestral protein, *sdY* lost the N-terminal DNA-binding domain, but preserved its C-terminal protein-protein interaction domain. Another interesting feature is that *sdY* is sex-linked in most salmonid species, indicating that it is a conserved SD gene in this teleost group. Yet, the SEX locus containing *sdY* is not located in the same chromosome in different salmonids species (Woram et al., 2003), suggesting a rapid turnover of sex chromosome while preserving what seems to be a jumping master SD gene (Faber-Hammond et al., 2015). How this unusual SD gene was recruited and the mechanism through which it regulates the downstream sex differentiation gene networks remains to be clarified. However, it presents a paradigmatic case that un-related genes outside the “usual suspects” are able to acquire *de novo* sex determining functions in teleosts.

What Lessons Can Be Learned From This Amazing Fish SD Gene Diversity?

The evolution of genetic sex determination mechanisms is closely linked to the evolution of sex chromosomes. The discovery of multiple new master SD genes in teleosts provided invaluable insights on the evolution of SD and the processes of the establishment of new sex chromosomes. Before the identification of the first fish master SD gene, models of sex chromosome evolution predicted that SD genes should evolve from a stepwise allelic diversification process starting from a single gene on an autosome. After fixation of a sex-specific allele in that newly formed SD gene, recombination reduction around that new sex locus in the proto-sex chromosome pair would give rise to classical heteromorphic sex chromosomes. Some newly described fish SD genes have evolved by this allelic diversification mechanism, for instance *sox3^Y* and *gsdfY* in some medaka species and *amhr2* in Takifugu. But this mechanism did not lead to strongly differentiated heteromorphic sex chromosomes in these teleost species. This phenomenon can probably be explained if we consider that these SD genes are very young in term of evolution. But the conservation of a single missense SNP in *amhr2* acting as the sole signal to initiate sex determination in at least three Takifugu species that diverged over 10 million

years ago, shows that recombination reduction around a new sex locus in the proto-sex chromosome is not necessary to fix a new SD gene. The characterization of new teleost SD genes also provided a novel mechanism for sex chromosome and SD gene evolution as many fish SD genes are the result of a duplication/insertion event. In these cases, a genomic area containing an ancestral gene is duplicated into a different chromosome that will initiate the formation of a new sex chromosome after subsequent functional and/or regulatory changes of the proto SD gene. This mechanism of gene duplication leading to sex chromosome formation first came in light for *dmr1/dmrt1bY* in Japanese medaka, and also been found to generate other vertebrate master SD genes, such as the female SD gene *DM-W* in the African clawed frog (*Xenopus laevis*) (Yoshimoto *et al.*, 2008).

In addition, thanks to their high turnover rate, teleost sex chromosomes also provide many different models to study the process of sex chromosome formation. One such case is from the study on half-smooth tongue sole in which a pair of relatively young Z and W chromosomes, comparing to those found in birds, have been sequenced and analyzed in details. This analysis showed that suppression of recombination, accumulation of transposable elements, fixation of sex specific genes, and gene dosage compensation are early events of sex chromosomes evolution. Furthermore, this half-smooth tongue sole W chromosome has already lost about two-thirds of its original protein coding genes and thus reached a roughly similar stage as much older mammalian and avian sex chromosomes within 30 million years. Combined with the finding that the gene-poor primate Y chromosome has been stable over the last 25 million years, they provide supports for the hypothesis that the decay of sex chromosome can happen rapidly in the early phase of sex chromosome formation then slow down and stabilize in its final stage, reaching a gene content equilibrium.

The 'limited options' hypothesis states that particular sex chromosomes or genes, especially those known to be involved in the SD gene network, might be preferentially recruited repeatedly in vertebrate lineages as new sex chromosomes or new master SD genes as they are 'good at doing the job' (Graves and Peichel, 2010). The multiple master SD genes recently found in teleost strongly endorse this idea as all of them with one single exception originate from three "usual suspect" gene family, namely *dmrt*, *sox* and *Tgf-β*. *Dmrt* and *sox* family members have also been also found in other vertebrate groups but several *Tgf-β* members have first emerged in teleosts as new 'usual suspects' and since then *Amh* has also been identified as the potential platypus master SD gene (Cortez *et al.*, 2014). Interestingly new knowledge on fish SD genes also provide an exception to this 'limited options' hypothesis as *sdy*, the salmonid master SD gene, is seemingly not related to any sex differentiation genes. However, it could not be excluded that this might be representing previously neglected factors in the SD gene networks (Herpin and Scharl, 2015), or that these unusual SD genes are underrepresented because they are just much more difficult to find.

Recently, a proposal with a developmental perspective has been put forward to view sex determination not as one hierarchical cascade with the master SD gene on the top, but as a complex network with different types of genetic and environmental factors influencing cell proliferation and hormone levels to push sexual development over either a male or female threshold (Heule *et al.*, 2014; Uller and Helanterä, 2011). Studies on the teleost SD provided supports to this view in which each node of the SD gene network has the potential of becoming the major-effect loci, not necessarily being on the top of the cascade. A prominent example of this hypothesis would be *amhr2* in Takifugu that modulate transduction efficiency of an upstream ligand signal, i.e., AMH acting on germ cell proliferation or regulating steroid synthesis activity (Kikuchi and Hamaguchi, 2013), to direct male or female development.

Many open questions still remain concerning teleost SD and probably the most important one is why the teleost fish use so many SD genes and SD systems with such a high sex chromosomes turnover rate? Rapid turnover of sex chromosomes is thought as a way to escape the decaying fate of sex chromosomes, assuming that the lack of recombination around the sex locus will lead to the accumulation of deleterious mutations. Alternatively, sexual antagonistic selection has also been put forward to explain the expansion of the sex locus and the accumulation of sex specific genes near it. Sex ratio selection provides a scenario that a new master SD gene could rise in frequency when it confers a more balanced sex ratio in the population. Other mechanisms such as random genetic drift and pleiotropic selection have also been used to explain the rise of new SD systems. Another hypothesis, explaining the lack of sex chromosome turnover in mammals and birds, proposes that these highly heteromorphic sex chromosomes might be acting as evolutionary traps that would stabilize SD genes for long span of evolutionary time (Bachtrog *et al.*, 2014). Interestingly, SD in many teleost species with a genetic SD system can still be influenced by environmental cues like for instance in the Nile tilapia and the half-smooth tongue sole. Transition stages between GSD and TSD are also well illustrated in the case of pejerrey species that conserves a SD gene (*amhY*) that is used alone in *O. hatcheri* and used in combination with temperature in the closely related species *O. bonariensis* (Yamamoto *et al.*, 2014). These transition stages could potentially facilitate the turnover of SD systems, leading to the emergence of new SD genes.

Glossary

Anurans Amphibians of the order Anura comprising frogs, toads and tree frogs, all which lack a tail in the adult stage and possess long hind limbs for jumping and swimming.

Epigenetics Heritable traits or phenotypes that cannot be explained by differences in DNA sequences; examples are DNA methylation and histone modification.

Gonadal primordium The region of the body, consisting of bipotential germ and somatic cell lines, from which the gonads will ultimately develop.

Gonochorists Species in which individuals develop as either male or female and remain the same sex throughout life (i.e., non-sex changing species).

Heterogamety Refers to the sex of a species that possesses different sex chromosomes (e.g., XY in human males).

Homogamety Refers to the sex of a species that possesses the same sex chromosomes (e.g., XX in human females).

Temperature-dependent sex determination (TSD) A type of environmental sex determination in which the temperature to which an animal is exposed during embryonic or juvenile development determines its sex.

Thermosensitive period The developmental period during which the germ and somatic cells of the gonads are sensitive to and may be influenced by temperature.

Urodeles Amphibians of the order Caudata that have a tail throughout life.

Vertebrates Animals from the subphylum Vertebrata consisting of 7 living classes: Agnatha, (jawless fishes), Chondrichthyes (cartilaginous fishes), Osteichthyes (bony fishes), Amphibia (amphibians), Reptilia (reptiles), Aves (birds), and Mammalia (mammals).

Introduction

Sex determination is the process by which the sexual fate of an organism is set into motion. This pivotal event subsequently dictates numerous aspects of an organism's life history, potentially including its morphology, growth, behavior, and lifespan. In vertebrates, sex determination may be driven by the presence and activation of a single gene, combination of genes, exposure to an environmental cue(s), or a combination of both genetic and environmental cues. This triggers a relatively conserved molecular signaling cascade and cellular and anatomical changes leading to the formation of either ovaries or testes from an undifferentiated gonadal primordium.

Although sexual reproduction (mating of a female and male) itself is highly conserved through vertebrate evolution, the process of sex determination exhibits a higher degree of plasticity. This is especially true for cold-blood or poikilothermic vertebrates (fish, amphibians and reptiles), which make up over half of all living vertebrates. Species from these classes exhibit a dizzying array of sex determination systems that have traditionally been categorized as either having a genetic (genetic sex determination, GSD) or environmental (environmental sex determination, ESD) basis (Fig. 1). Nature defies these categories, however, as an ever-growing number of species previously thought to exhibit strict GSD or ESD demonstrate interplay between genetic and environmental cues leading to the ultimate female or male sexual phenotype.

The diversity of sex determination mechanisms in cold-blooded vertebrates has been driven by millions of years of radiation and adaptation to extreme aquatic and terrestrial environments. This exciting research area truly stands at the intersection where genetics meets environment and is important to our understanding of the evolution of sex determination mechanisms and sexual reproduction. The goal of this article is to provide a general summary of sex determination in cold-blooded vertebrates, including recent developments in the field and vital questions that remain.

Genetic Sex Determination

In nearly all mammals, including humans, sex is irreversibly determined at conception by the presence/absence of the sex-determining region of the Y-chromosome (*SRY*). If the *SRY* gene is paternally inherited and properly expressed, testicular development is triggered, whereas in the absence of *SRY*, ovarian development is initiated. This type of system is referred to as monogenic because it is controlled by a single sex-determining locus or 'master switch' that initiates the sex differentiation cascade. This

Fig. 1 The variety of sex determination systems in cold-blooded vertebrates. Environmental sex determination (ESD) is common in reptiles and observed in a few fishes. The major genetic sex determination (GSD) systems, ZW/ZZ and XX/XY, are found in all classes of cold-blooded vertebrates, although some species are sensitive to environmental factors and GSD can be influenced/overridden (GSD+environmental effects), at least under experimental conditions. Complex polygenic systems are observed in some fishes but considered rare.

relatively simple and highly conserved system in mammals is in stark contrast to what is seen in cold-blooded vertebrates. Indeed, these vertebrate classes exhibit a multitude of GSD systems ranging from monogenic to complex multi- and polyfactorial (polygenic) systems that are still not well understood (Fig. 1).

There are numerous examples of monogenic GSD in cold-blooded vertebrates. So-called XX/XY and ZW/ZZ systems are most common and appear to have evolved independently numerous times in some taxa. In XX/XY systems, like that of humans, males are the heterogametic sex (XY genotype) and females the homogametic sex (XX genotype). The opposite holds true for ZW/ZZ systems; females are heterogametic and males are homogametic. This basically means that sex is determined by the genetic contribution of the male parent in XX/XY species and the female parent in ZW/ZZ species. This does not mean however that the same gene or genes on the sex chromosomes determines sex for all XX/XY or ZW/ZZ species. In fact, in some taxa there appears to have been high turnover of master sex-determining genes as we discuss later.

GSD in Fishes

Many fish species are in the process of what is considered initial sex chromosome differentiation and possess 'homomorphic sex chromosomes,' which do not noticeably differ in appearance from autosomes (Penman and Piferrer, 2008). In contrast, some species have 'heteromorphic sex chromosomes,' which differ in cytological appearance. For example, the human Y-chromosome has undergone significant reduction in the number of genes it possesses and its overall size during evolution, making it easily distinguishable from autosomes by karyotype.

Systems of GSD have primarily been characterized in model fishes (e.g., medaka *Oryzias latipes*) and species of importance related to aquaculture (e.g., Nile tilapia *Oreochromis niloticus*; rainbow trout *Oncorhynchus mykiss*; pufferfish *Takifugu rubripes*). Identification of a species' sex determination system is often achieved through chromosome set manipulation (e.g., gynogenesis) and/or sex reversal and progeny testing (Devlin and Nagahama, 2002). Unlike mammals, which become refractory to sex steroid treatment, the processes of sex determination and gonadal differentiation in most cold-blooded vertebrates can be easily overridden by exogenous treatments during what is referred to as the labile or critical-sensitive period of development, which varies by species. Sex reversal typically involves immersion and/or dietary treatment of animals with either androgens, estrogens, or inhibitors of steroid synthesis (e.g., aromatase inhibitors (AIs); Fig. 2). These approaches can be used directly or indirectly to produce monosex stocks of fish for aquaculture, which is not only important from an applied perspective, for example, one sex exhibiting superior growth in aquaculture, but can also reveal the underlying GSD system (Fig. 2).

XX/XY and ZW/ZZ GSD systems are most common in fishes, with XX/XY being predominant (Fig. 1). Examples of species with a known XX/XY system include medaka, rainbow trout, Japanese flounder (*Paralichthys olivaceus*), Atlantic halibut (*Hippoglossus hippoglossus*), and sablefish (*Anoplopoma fimbria*). Examples of species with a ZW/ZZ system include yellowtail (*Seriola quinqueradiata*), blue tilapia (*Oreochromis aureus*), and half-smooth tongue sole (*Cynoglossus semilaevis*). There are also cases in which the system of sex determination differs among species of the same genera (e.g., within *Oryzias* and *Xiphophorus*) and even within a species (e.g., *Xiphophorus maculatus*; Devlin and Nagahama, 2002). Thus, there appears to be no strong genetic selection for male versus female heterogamety in fishes.

Variation on major GSD systems above has also been documented, as some fishes exhibit systems (XX/XO and ZW/ZO) in which one sex chromosome has been lost in males (Devlin and Nagahama, 2002; Penman and Piferrer, 2008). Females thus inherit two sex chromosomes (XX or ZW) while males inherit a single sex chromosome (X or Z). In these cases, "O" in the nomenclature

Fig. 2 Example of sex reversal techniques and progeny testing often used by researchers to identify the underlying sex determination system of cold-blooded vertebrate species. By exogenously treating a cohort of animals with an androgen or aromatase inhibitor (AI) during the sexually labile period, approximately half the individuals can be masculinized (e.g., XX male). When the treated animals are subsequently crossed with females, sex ratios of the progeny can be tested to potentially determine the mode of sex determination. For example, if 100% female progeny are obtained from half the crosses, it strongly suggests the species is XX/XY. Alternative sex ratios would suggest either a ZW/ZZ species or that other (polygenic GSD or ESD) mechanisms are involved. Estrogen treatments can alternatively be used to feminize cold-blooded vertebrates and similar breeding schemes performed.

denotes the lack of a second sex chromosome. Additionally, there are cases of multiple sex chromosome systems (e.g., XX/X_1X_2Y ; ZW_1W_2/ZZ) in which chromosomal fusions have given rise to females and males having a different diploid number of chromosomes.

Observation of sex ratios that do not fit any of the above patterns often indicates either a polygenic system or an influence of environmental factors, such as temperature (Fig. 2; see ESD section below). Polygenic systems are considerably more rare than monogenic ones and considered transient or intermediate states toward establishment of a monogenic system (Penman and Piferrer, 2008). Well-studied examples of polygenic systems are live-bearing species of platyfishes and swordtails (genus *Xiphophorus*) and the widely used model species, zebrafish (*Danio rerio*). In the case of zebrafish, sex determination differs among wild and domesticated strains and may involve four or more different chromosomes, as well as environmental factors.

GSD in Amphibians

Similar to fishes, GSD systems in amphibians have largely been identified through gynogenesis and/or sex reversal and progeny testing (Fig. 2). Research has shown that most amphibians have homomorphic sex chromosomes and either an XX/XY or ZW/ZZ system (Fig. 1). Most urodeles (salamanders) and anurans (frogs) of the genus *Rana* have an XX/XY system, whereas the well-known model frog species, *Xenopus laevis*, toad (*Bufo bufo*), and urodeles of the genus *Ambystoma* have a ZW/ZZ system (Nakamura, 2009).

Data indicate that the ancestral anuran (Leiopelmatidae) had a ZW/ZZ system, suggesting that ZW/ZZ may be ancestral to XX/XY systems in amphibians. However, evidence indicates that sex chromosomes have evolved numerous times in this lineage. Also as in fishes, within-species differences in the sex determination system have been documented. The pond frog (*Rana rugosa*) for instance exhibits either an XX/XY or ZW/ZZ system depending on its local population in Japan (Nakamura, 2009). Interestingly, the local pond frog populations even have different sex chromosome morphology. This variability within and among species again underscores the lack of selection for one particular GSD system in most cold-blooded vertebrates.

Sex ratios of some amphibians can also be affected by exposure to extreme low or high temperatures, outside of what the species would normally experience in nature ("thermal sex reversals"), but amphibians are still generally considered GSD species. It is worth noting however that temperature experiments have been conducted in very few amphibians and recent studies suggest that epigenetics may be important to sex determination in some species (e.g., European common frog, *Rana temporaria*).

GSD in Reptiles

Many reptile species exhibit ESD, however all snakes and some lizards and turtles exhibit GSD (Fig. 1; Janzen and Krenz, 2004). Consistent with fishes and amphibians, there are examples of both XX/XY and ZW/ZZ systems in reptiles. All snakes investigated to date are ZW/ZZ, while turtles and lizards with GSD have either a ZW/ZZ or XX/XY system (Fig. 1). Some examples of reptiles with a documented XX/XY system are the green iguana (*Iguana iguana*), tokay gecko (*Gekko gecko*), and musk turtles (genus *Staurotypus*). In addition to snakes, examples of ZW/ZZ species include racerunner lizards (genus *Eremias*), leaf-toed geckos (genus *Phyllodactylus*), and Komodo dragon (*Varanus komodoensis*).

Ancestral reptiles are generally thought to have exhibited ESD, but there is still debate regarding whether ESD or GSD came first. Based on phylogeny there appears to be no clear segregation of species into particular systems, aside from snakes (all ZW/ZZ, no ESD), iguanas (stable XX/XY), and crocodilians (all ESD). Another general observation is that ZW/ZZ systems are rare in turtles compared to lizards. That said, most genera of turtles exhibit ESD.

Environmental Sex Determination

Environmental sex determination is a form of sex determination in which non-genetic (environmental) cues serve as the master determinant of sex. ESD is generally considered a more primitive sex determination mechanism, which was largely replaced by the evolution of sex chromosomes and establishment of GSD. Yet, it has persisted in some reptiles and fishes and offers a high degree of plasticity that may hold fitness advantages. Prevailing theory proposed by Charnov and Bull (1977) indicates that ESD is advantageous when environmental conditions are patchy and different fitness levels exist for each sex (examples below).

Conventionally, GSD and ESD have been considered mutually exclusive systems. However, based recent discoveries, revealed in some cases via genomics technologies (e.g., next-generation sequencing), there are few if any cases of ESD that do not involve the genome or epigenome in some way. This new information is shifting the field's view of ESD, and whether classically defined ESD (i.e., that only influenced by non-genetic factors) exists.

In recent years there has also been accumulating evidence for what has been referred to as "thermal sex ratio distortions" or "anomalous GSD," which applies to cases where environmental factors influence sex determination and/or differentiation, and ultimate sexual phenotype, but effects may not be relevant in the natural environment (Conover, 2004; Ospina-Álvarez and Piferrer, 2008). An example of this would be exposure of a species to extremely low or high temperatures that result in skewed sex ratios (Fig. 3). It is generally accepted that amphibians only exhibit such thermal sex ratio distortions, not ESD (Nakamura, 2009). Therefore, the sub-sections below focus solely on fishes and reptiles.

ESD in Fishes

Environmental influences on sex determination/differentiation have now been documented in well over 50 species of fish (Devlin and Nagahama, 2002; Conover, 2004; Ospina-Álvarez and Piferrer, 2008). By far the most prevalent environmental factor

Fig. 3 Major observed patterns of temperature effects on sex determination in fishes and reptiles. Most commonly in fishes, increasing water temperatures significantly reduce female proportions (A–B). In some flatfishes, exposure to low or high temperatures reduce female and increase male proportions (C). It remains unclear whether patterns A and C represent environmentally relevant ESD or anomalous GSD, because sex ratios are stable at intermediate temperatures that might reflect the natural environment. In reptiles, low temperatures may induce high (D) or low female proportions (E) with the patterns flipping at higher temperatures. Other reptiles exhibit a female-male-female pattern (F) with high female proportions at low and high temperatures and high male proportions at intermediate temperatures. Based on Conover, D.O., 2004. Temperature-dependent sex determination in fishes. In: Valenzuela, N., Lance, V.A. (Eds.), *Temperature-Dependent Sex Determination in Vertebrates*, pp. 11–20. Washington: Smithsonian Books.

influencing sex is temperature (temperature-dependent sex determination; TSD). The first fish in which TSD was documented was the Atlantic silverside (*Menidia menidia*, family Atherinopsidae). In Atlantic silversides, exposure to different water temperatures during what is known as the thermosensitive period, occurring during early larval development, can affect sex determination. Atlantic silversides have an “annual” life cycle and attain maturity within 1 year. Sex ratios in this species are female-biased at colder temperatures at the beginning of the breeding season, however warmer temperatures later in the breeding season induce male-biased sex ratios (Fig. 3(B)). This is because reproductive fitness (e.g., body size, fecundity) is higher in females than males, and thus being born earlier and having a longer breeding season is more beneficial to females than males (Conover, 2004).

There is also geographical variation in the TSD response in Atlantic silversides (Conover, 2004; Duffy et al., 2015). Interestingly, no populations display pure TSD or GSD, but the level of TSD is uniformly high in their southern range and then declines rapidly approaching their northern range, where GSD dominates. The level of TSD then rebounds to a moderate level in northern-most populations. The length of the growing season and high gene flow among populations is what likely drives this latitudinal variation in the TSD response. As mentioned above, longer growing seasons are more beneficial to females than males. In lower latitude areas, cooler water temperatures during larval development signal a longer growing season compared to higher latitude areas. Following the Charnov and Bull model, female reproductive fitness would thus be enhanced in southern populations by TSD, whereas fitness is maximized for individuals born late in the season by developing as males, which have a better chance of reproducing at a smaller body size than do females.

Another Atherinid species, pejerrey (*Odontesthes bonariensis*), native to South America presents one of strongest known TSD responses in fishes (Strüssman et al., 1997). Monosex female or male stocks of pejerrey can consistently be produced when larvae from different broods are exposed to environmentally relevant temperatures of 17°C or 29°C, respectively. Recently, the master sex-determining gene, *Y-chromosome specific anti-Müllerian hormone (amhy)*, was discovered in *O. hatcheri*, a congeneric species that exhibits GSD. The homolog of *amhy* was then identified in pejerrey and it was demonstrated that its presence or absence favored male or female development, respectively, when fish were reared at a sexually neutral temperature (Yamamoto et al., 2014). Together, these results in Atherinid fishes indicate that despite the conventional view of ESD and GSD being autonomous mechanisms, the presence of ESD does not exclude the possibility of underlying GSD mechanisms.

In addition to temperature, several other environmental factors may influence fish sex ratios (Baroiller et al., 2009; Heule et al., 2014). An effect of pH on sex determination has been observed in swordtail and some Cichlid species. In the swordtail (*Xiphophorus helleri*), for instance, acidic water induces all-male populations, while a neutral pH produces mostly females. Fish density is also known as an environmental factor that can modulate sex ratios. In eels, both field and laboratory observations revealed that low densities tend to favor female development, while high densities favor males. Even the color of the rearing enclosure can influence sex. In southern flounder (*Paralichthys lethostigma*), rearing fry in blue-colored tanks can induce significantly male-biased sex ratios compared with black or gray tanks (Mankiewicz et al., 2013). This is in addition to documented temperature effects on sex ratios in this and other flatfish species (Luckenbach et al., 2009).

Clearly many environmental factors can influence sex determination/differentiation in fishes. However, the underlying mechanisms, interactions with GSD mechanisms, and potential fitness advantages among the sexes remain largely unknown. Indeed, a significant shortcoming in this field has been the dearth of field studies focusing on whether observations of environmental effects observed in captivity occur in wild populations. Of the 50+ species for which experimental temperature effects have been reported, ESD has only been confirmed in a few Atheriniform species and Nile tilapia (*Oreochromis niloticus*).

ESD in Reptiles

All crocodilian and many turtle species exhibit ESD (Fig. 1; Lang and Andrews, 1994). These egg-laying species bury their eggs below ground where the embryos develop until they hatch and depart the nest. Studies indicate that the depth and position of eggs within a nest can influence the temperature exposure (higher in the nest=warmer; lower=cooler) and determine the sex of individual offspring. Temperature exerts this affect during the thermosensitive period of embryogenesis, which is typically around the mid-trimester of development.

As in fishes, TSD responses in reptiles vary considerably by species. In crocodilians, a female-male-female pattern is ubiquitous (Fig. 3(F)). For example, in American alligator (*Alligator mississippiensis*), if embryos are incubated below 31.5°C or above 35°C during the thermosensitive period, monosex female populations can be obtained, while the percentage of males increase and reach 100% at 32.5–33.0°C and subsequently decline (Lang and Andrews, 1994). On the other hand, red-ear slider turtle (*Trachemys scripta*) exhibit a male-female pattern of TSD where incubation of embryos at 26 or 31°C produce monosex female or male populations, respectively (Fig. 3(E); Wibbels et al., 1991).

Another fascinating case that highlights the interplay between ESD and GSD mechanisms is the Australian central bearded dragon (*Pogona vitticeps*). This species has a ZW/ZZ system, however high temperature may override this GSD system and induce female sex reversal (i.e., production of ZZ females) under experimental conditions. It was recently reported that female sex reversal can also occur naturally in wild dragon populations and that sex-reversed females are viable and fertile (Holleley et al., 2015). Further, levels of GSD versus TSD were compared among progeny from ZW and sex-reversed ZZ mothers, in both cases mated with normal ZZ males. Progeny from normal ZW mothers were dominant in the range of 22–32°C (phenotypic sex ratio of 1:1), but temperature began to interact with and override GSD above 32°C. Conversely, in progeny from sex-reversed ZZ mothers, sex was determined solely by temperature, with no genetic influence observed. The female W-chromosome was thus eliminated from the lineage in just a single generation. This demonstrates a rapid transition under experimental conditions from

a predominantly GSD system (with heteromorphic sex chromosomes) to an ESD system (Holleley *et al.*, 2015). Although it has not been possible to clarify sex-specific fitness differences that could cause a transition from GSD to ESD, this rapid transition provides an alternative mechanism to the prevailing view that ESD evolves, or is maintained, in response to a sex-specific fitness advantage.

Mechanisms and Key Players

Recently Identified GSD and ESD Mechanisms

As discussed above, GSD is typically triggered by the expression of a paternally- or maternally- inherited master sex-determining gene(s) that may be species or even population specific. Advancement of genomics approaches has led to significant progress in the identification of master sex-determining genes in cold-blooded vertebrates, particularly in fishes (Heule *et al.*, 2014; Pan *et al.*, 2016). Interestingly, warm-blooded vertebrates, like mammals and birds, show a high degree of conservation in master sex-determining genes; nearly all mammals use *SRY* and most or all birds use a transcription factor, *DMRT1*. Fishes on the other hand appear to have experienced high turnover of sex-determining genes, with some exceptions. Just within the genus *Oryzias*, three unique sex-determining genes have recently been identified, two transcription factors (*dmrt1bY* and *sox3Y*) and one transforming growth factor (*gsdfY*). High gene turnover among these closely related species contrasts with conservation of *sdY*, a former immune-associated gene, as the master sex-determining gene in all salmonid fishes (genera *Salmo*, *Oncorhynchus*, *Salvelinus*). The reason for the evolution of such a high number of sex-determining genes in fishes and variability among genera is unknown, although with identification of more master genes, a pattern based on life history or phylogeny may ultimately arise.

With regard to amphibians, the GSD mechanism is best characterized in *Xenopus laevis*, which as mentioned above, has a ZW/ZZ system. The master sex-determining gene in this species is *DM-W*, a paralog of *Dmrt1*, which was identified on the female W-chromosome (Yoshimoto *et al.*, 2008). *Dmrt1* is a key upstream inducer of male development in *X. laevis* and other vertebrates. In ZW individuals, *DM-W* inhibits transcription of *Dmrt1*, which in turn inhibits the male pathway and induces female development. So far, *DM-W* is the only sex-determining gene identified in amphibians and only “W-linked,” female sex-determining gene identified in any animal.

For decades little has been known about how TSD occurs in reptiles; however, recent studies have led to several important discoveries. In the American alligator it was recently revealed that thermosensitive transient receptor potential (TRP) channels can act as molecular environmental sensors and are involved in the masculinization process during TSD (Yatsu *et al.*, 2015). Also, in red-eared slider turtle, it was demonstrated that *Dmrt1* may be a master gene associated with the TSD response (Ge *et al.*, 2017). Experiments showed that *Dmrt1* is both necessary and sufficient for masculinization of slider turtles, and importantly, that environmental temperature affects the DNA methylation pattern in a sex-specific manner in the promoter region of *Dmrt1*. This would be considered an epigenetic effect, as DNA methylation is one type of epigenetic mark that can influence gene transcription.

Another epigenetic mechanism is chromatin modification, which was highlighted in a new study with broad implications to reptile TSD. This study revealed that intron retention in *Jumonji* chromatin modifier genes (*JARID2/JMJD3*) is favored by extreme rearing temperatures in Australian central bearded dragon, affecting gene function and altering the epigenetic landscape (Deveson *et al.*, 2017). A cold-inducible RNA-binding protein (CIRBP) is thought to be responsible for intron retention during thermal stress.

Epigenetic regulation of genes involved in sex determination/differentiation has also been documented in fishes. For example, the promoter region of the *cyp19a1* gene (also known as aromatase), which encodes the rate-limiting enzyme responsible for estrogen production, is affected by high temperature exposure in European sea bass (*Dicentrarchus labrax*; Navarro-Martín *et al.*, 2011). This also occurs through differential methylation and leads to male development in genotypic female fish. In addition, differential DNA methylation has recently been documented in the *Dmrt1* gene of half-smooth tongue sole and linked to transgenerational sex effects (Shao *et al.*, 2014). These important recent discoveries in cold-blooded vertebrates provide evidence for genetic and epigenetic regulation of ESD, and plausible links between environmental factors and downstream processes associated with sex differentiation.

Conservation of Downstream Players

Regardless of the sex determination mechanism, downstream signaling associated with gonadal sex differentiation appears to be highly conserved among vertebrates and to reflect antagonistic pathways leading to either ovarian or testicular differentiation. In cold-blooded vertebrates, sex-specific downstream patterns of gene expression related to steroid biosynthesis and differences in steroid production are ubiquitous (Devlin and Nagahama, 2002; Trukhina *et al.*, 2013). A now classic example of this is *cyp19a1*/aromatase, which appears to have a highly conserved role in ovarian development and maintenance, and is thought to be major factor in TSD. This is supported in part by steroid, AI, and temperature-induced sex reversal in numerous species discussed above.

Conversely, androgen production appears to be an important component of testicular differentiation and development in many cold-blooded vertebrates. Treatment with androgens can generally masculinize genotypic female individuals (Fig. 2). However, interestingly, no studies to our knowledge have demonstrated a masculinizing effect of androgens in reptiles.

Environmental effects on sex ratios have also been linked to changes in production of gonadal steroids, such as estrogens and androgens. In addition, there is evidence that cortisol, the major glucocorticoid (stress hormone) produced by the adrenal gland, is a key player in the mechanism underlying ESD. In Japanese flounder (*Paralichthys olivaceus*), high temperature increases cortisol

production and causes masculinization of genotypic females by directly suppressing *cyp19a1* gene expression and estrogen production (Yamaguchi *et al.*, 2010). Elevated cortisol was also correlated with masculinizing effects of tank color in southern flounder. Furthermore, pejerrey larvae exposed to masculinizing temperatures display significantly elevated whole-body cortisol and 11-ketotestosterone (a potent androgen in fishes) levels, along with testis-like gene expression patterns (Fernandino *et al.*, 2013).

Conclusions and Future Considerations

Mechanisms of sex determination are highly variable in cold-blooded vertebrates; much more so than in warm-blooded vertebrates like mammals and birds. Two major systems of GSD (XX/XY and ZW/ZZ) are found in cold-blooded vertebrates and coexist with ESD in fishes and reptiles. In addition, there are examples of slight variation on these major systems, as well as complex, polygenic systems. Among cold-blooded vertebrates, GSD systems appear to show no clear phylogenetic segregation, suggesting there is little or no evolutionary pressure toward a unified system. This is further supported by the fact that the major GSD systems have independently evolved numerous times in closely related species, and in some cases even co-occur within a species.

ESD is generally considered a highly plastic, ancestral mechanism, yet this form of sex determination has stood the test of time. Reptilian species with ESD are numerous, whereas environmentally relevant ESD has only been ascribed to a few fishes and no amphibians. Still, there are numerous reports of environmental effects (e.g., temperature, pH, density) on sex ratios. Some of these cases are considered anomalous, thermal sex ratio distortions. However, more field-based experiments are needed to conclude on the prevalence of ESD. Mounting evidence also indicates that GSD and ESD are not mutually exclusive mechanisms, as once believed, and that even in classical ESD species, the genome and/or epigenome play important roles. As noted by Bull (2015), GSD and ESD mechanisms can each be highly functional and adaptive, and may, in theory, evolve back-and-forth along an evolutionary progression.

The high degree of variance in sex determination among cold-blooded vertebrates may leave one with the impression that there is little semblance of order in this biological event. However, downstream processes, such as those associated with steroid biosynthesis, appear to be highly conserved. This suggests that there are several paths toward the same outcome, and that upstream mechanisms can change/shift, as long as critical connections to factors that drive development of the two sexes are maintained.

We also touched on several cases of stability in sex determination in this article. A prime example of this is snakes, which all exhibit GSD and a ZW/ZZ system, despite the fact that their fellow reptilians have diverse sex determination mechanisms. While there are several theories as to why snakes display this remarkable stability (e.g., shorter lifespan), the answer remains unknown.

Given the intimate association of cold-blooded vertebrates with their immediate environment, especially with regard to temperature, it is not altogether surprising that they have maintained a higher level of plasticity in some physiological mechanisms relative to warm-blooded vertebrates. The fact that TSD has not been replaced in some extremely old vertebrate taxa (e.g., crocodilians) is intriguing. One might imagine that millions of years of environmental change and evolutionary pressure would have forced such change. Yet, TSD persists. One possibility is that natural environmental change typically occurs very slowly, allowing time for adaptation of ESD mechanisms. This is not the case, however, with climate change currently being driven by anthropogenic causes. The question now is whether species with TSD will be able to survive in this rapidly changing world, and if species with GSD may begin to display well-documented thermal sex ratio distortions, previously observed only in the laboratory. Skewed sex ratios resulting from these scenarios could put extreme pressure on survival of temperature-sensitive, cold-blooded vertebrates.

Sex Determination and Gonadal Development in Birds

Introduction

Sex determination initiates the process of sexual differentiation in developing embryos, generating the distinct sexual phenotypes that support the different systems of sexual reproduction observed across vertebrates. Sex determination mechanisms are varied; some are genetic (mammals, birds), some are environmental (crocodiles, primitive lizards) and some species adopt various combinations of both (fish, turtles; Barske and Capel, 2008). Mammals and birds both utilise genetic sex determination (GSD) mechanisms and while these share many molecular components with conserved functions, they have evolved independently.

The majority of information on mammalian sex determination derives from studies in the mouse, principally because the mouse is a relatively inexpensive, well-established model that is easily bred, manipulated and analysed. This knowledge has been complemented by observational studies of sex determination disorders in humans and by comparative genomic analyses in other mammalian species. The mammalian sex determining mechanism is one of Y-chromosome dominance, in which the Y-linked testis-determining gene, sex-determining region Y (SRY), is present and highly expressed in the gonads of heterogametic males (carrying XY) inducing a male gonadal phenotype, but that is absent in homogametic females (carrying XX), with the result that a female gonadal phenotype develops. In mammals, secondary sex determination (the appearance of secondary sexual characteristics) is principally regulated by gonadal hormones.

In contrast to mammals, female birds have heterogametic sex chromosomes (carrying ZW) while male birds are homogametic (carrying ZZ). In addition, efforts to identify an SRY gene in the avian genome, have been unsuccessful. Historically, the chick embryo has been used extensively as a model system for vertebrate embryonic development and has many advantages (Clinton *et al.*, 2016); not least are the accessibility of the developing embryo in the egg, the availability of large numbers of synchronised fertilised eggs, and the low cost of eggs. In recent years it has been considered an ideal comparative model system to study vertebrate sex determination and gonadal development. In the following sections we will present an overview of sex determination and gonadal differentiation in birds, principally focused on the chicken and including comparisons with the mammalian counterparts where appropriate.

Morphology of the Developing Avian Gonad

In general terms, the basic gonadal structure is well-conserved between avian and mammalian species, but there are many aspects of gonadogenesis that differ significantly between these classes of vertebrates. The genital ridges are the first visually distinct precursors of the gonads and in the chick these form from the intermediate mesoderm of the embryo on embryonic day three (E3) of development. The ridges form in symmetrical locations on either side of the developing gut, on the surface of the emerging mesonephroi (primitive kidneys). Over the following days, the precursors for steroidogenic cells, supporting cells, interstitial cells and primordial germ cells (PGCs) colonise the gonad, begin to proliferate and differentiate to form the characteristic structures of the male and female gonads. At this early stage in both male and female embryos, the surface epithelial layer of the left gonad is markedly thicker than that of the right gonad; in males this layer thins as development proceeds such that the gonads on both sides are equivalent. In the left female gonad, the surface epithelium further thickens into a structure known as the cortex, while the right female gonad ceases development. Sex cords form in the core region known as the medulla, and while these later degenerate in females, in males these develop into the seminiferous tubules. The PGCs, which are initially distributed throughout the gonads, are enclosed by the sex cords in both male gonads where they proliferate and will differentiate into spermatogonia. In females, the PGCs in the left gonad migrate into the cortex where they proliferate and eventually form oögonia.

In order to contribute to the gonad, the PGCs follow a complex migration route from their site of formation. These cells are thought to arise in the period immediately following fertilisation, when their fate is specified by maternal induction through a mechanism known as preformation. This specification is achieved through a maternally deposited cytoplasmic constituent termed germ-plasm, which contains VASA, a protein specific to PGCs. In contrast, mammalian PGCs are specified via a different process known as epigenesis where individual cells are induced via a bone morphogenetic protein (BMP) – dependent signalling pathway which occurs at a later stage of development (Table 1; Nakamura *et al.*, 2013). Following specification, PGCs are located in an area known as the zona pellucida in the centre of the early chick embryo, from whence they migrate cranially to the edge of the extra-embryonic region (E1) and subsequently into a region anterior to the embryonic head on known as the germinal crescent (E2). From this location, between E2 and E3, they enter the developing vascular system and migrate through the circulation and then the dorsal mesentery to enter the embryonic gonad around E3.5 – presumably under the influence of chemo-attractants. This migration route differs from that seen in mammalian species, where PGCs migrate from the proximal epiblast (where they are specified), through the allantois, the endoderm (future hindgut), then the mesonephros, to reach the gonad (Sekido and Lovell-Badge, 2007; Richardson and Lehmann, 2010).

At the time of PGC migration, somatic cells also migrate into the developing gonad. In both sexes, the precursors of the steroidogenic and other supporting cells migrate from the nephrogenic mesodermal mesenchyme into the developing gonad from

approximately E4 (Sekido and Lovell-Badge, 2007). In contrast, in mammals, the supporting cell precursors are known to migrate to the early gonad directly from the coelomic epithelium rather than the nephrogenic mesenchyme. These cells are the precursors of Sertoli cells in male and granulosa cells (GC) in females, and support PGC survival and differentiation. The steroidogenic cell precursors are also found within this migrating population and will give rise to Leydig cells in the male and theca cells in the female. In the chicken, non-steroidogenic interstitial cells migrate from the coelomic epithelium at the same time that laminin-1 expression ceases in the coelomic epithelium surrounding the gonads, and it is thought that this is representative of changes that allow the movement of cells across embryonic compartments (Sekido and Lovell-Badge, 2007).

For a short period after sex determination in chicks (E5-E6) the gonads of females and males remain indistinguishable with the medulla in both sexes developing sex cords (Sekido and Lovell-Badge, 2007). This stage of development in the mouse differs from the chick, in that the female mouse gonads do not acquire primitive sex cords.

In the medulla of the male chick by E7, tubules have formed that contain Sertoli cells surrounding PGCs. These tubules are surrounded by interstitial tissue, containing blood vessels, nerves, epithelial cells and Leydig cells and eventually join up to form the seminiferous ducts. In addition, the seminiferous tubules will be surrounded by fibroblast-like cells and myoid/peritubular cells (Rothwell and Tingari, 1973). In the mouse, the tubules are also lined with myoid cells which appear from E12.5. Myoid cells are not present in tubules in the chicken gonad even by E14, suggesting that these cells may appear later in development in avian species (Table 1; Sekido and Lovell-Badge, 2007). In both gonads in the male chick embryo, PGCs differentiate into spermatogonia from E13 onwards, and from approximately 10 weeks post-hatch, PGCs undergo further cell division and differentiation until the time of sexual maturity (~16 weeks) when spermatogenesis begins.

In female chick embryos, the structures equivalent to the male seminiferous tubules are called medullary cords, and form at the same developmental time (E7; Bellairs and Osmond, 2014). These primitive sex cords do not fuse into tubules/ducts but develop into epithelial-lined spaces known as medullary lacunae. The left female gonad develops a thickened cortex which contains PGCs and pre-granulosa cells that have migrated from the medulla, while the epithelium of the right gonad remains undifferentiated. Female PGCs begin differentiation earlier than male PGCs to form primary oocytes (E8) and enter meiosis I at E13, pausing at prophase I prior to hatching. Around the same time, these primary oocytes undergo a significant reduction in numbers by apoptosis, and then the survivors remain in meiotic arrest until shortly before ovulation. The germ cells proceed through meiosis I and those selected for ovulation enter meiosis II, and arrest at metaphase II until ovulation, when meiosis is completed.

Table 1 summarises the major morphological differences between avian and mammalian gonadal development.

The adult ovaries of birds and mammals are markedly different (Johnson, 2015). In mammals, pre-ovulatory follicles contain a fluid-filled compartment called the antrum which surrounds the oocyte-cumulus complex, and which increases in volume as the follicle grows. Avian follicles do not contain a fluid-filled compartment, and the growing yolk/oocyte is responsible for most of the follicular size. In mammals, follicular maturation is accompanied by the acquisition of granulosa cell (GC) layers to the follicular wall, and pre-ovulatory follicles typically have up to 6 layers of GCs. In contrast, at ovulation the chicken oocyte is surrounded by a single layer of GCs. In addition, avian GCs do not express the aromatase enzyme (Cytochrome P450 Family 19 Subfamily A Member 1 or CYP19A1), and consequently do not produce estrogens, while mammalian GCs do express aromatase and one of their primary functions is to convert theca-derived androgens into estrogen. In the chicken, the majority of aromatase is produced by the cells of the theca externa which comprises the outer layer of the growing follicle. Mammals and birds also differ in the nature of the follicular selection process: in mammals, follicles are selected for growth in cohorts of which one or more (depending on the species) will become dominant and ovulate while the remaining (subordinate) follicles will undergo atresia. In birds, individual

follicles are selected on a regular basis and growth is initiated. This generates a hierarchy of growing follicles which ovulate in sequence. This allows the laying of multiple eggs and the subsequent production of more offspring in a short period of time compared to mammals.

In the chicken, full ovarian development is restricted to the left gonad and by the midpoint of embryogenesis, the right ovary is significantly smaller than the left and lacks a thickened cortex. This is attributed to a failure of the paired-like homeodomain transcription factor 2 (PITX2) – steroidogenic factor (SF1) – cyclin D1 pathway to be activated in the right gonad, leading to a lack of estrogen sensitivity and a reduction in cell proliferation (Ishimaru *et al.*, 2008). Despite this, during the early stages of gonadal development, the right ovary is steroidogenically active. This left-right asymmetry in gonadal development is only one of a number of differences between bird and mammalian gonadal development (Table 1).

Mechanisms of Sex Determination in Birds

There is significant diversity in the sex determining mechanisms utilized by vertebrates (reviewed in Bachtrog *et al.*, 2014). The mechanism common to mammals and birds is described as GSD, and versions of GSD have also been described in amphibians, and some other reptiles and fish (Bachtrog *et al.*, 2014). This mechanism reflects the acquisition of different sex chromosomes in males and females, which are thought to have evolved gradually from autosomal chromosome pairs. In some cases there is a single sex-determining gene on a sex chromosome, however in other species there are multiple genes which drive sex determination (Barske and Capel, 2008). The vast diversity of the available sex-determining mechanisms reflects the speed with which these evolve and the high number of independent paths taken across vertebrate species.

The most well-known example of a heteromorphic sex-chromosome system is that of the mammals, where the male is heterogametic with one X and one Y chromosome, and the female is homogametic, with two X chromosomes. Although, the Y-chromosome is greatly reduced in size compared to the X and carries few functional genes, the sex determining mechanism is one of Y-dominance, where the presence of a Y chromosome is sufficient to induce testes and results in a male phenotype. This system was originally elucidated through analyses of individuals that carry XO chromosomes (who develop as females) and those that carry XXY chromosomes (who develop as males). As discussed in the next section, Y dominance is primarily established through a master sex (testis) determining gene, SRY.

Birds and a number of snakes and reptiles, where the female is the heterogametic sex, are described as possessing a ZW sex chromosome system. In birds, the male is the homogametic sex, with two Z chromosomes (ZZ) while the female is heterogametic, with one Z and one W chromosome (ZW). With the exception of ratite birds (flightless birds such as the ostrich and emu) the W chromosome is significantly smaller than the Z chromosome. Excluding the ratites, the sex chromosomes of different birds have evolved from a common pair of autosomes (Fridolfsson *et al.*, 1998). It is clear from the lack of homology between mammalian and avian sex chromosomes that these have evolved independently of each other.

One important factor that determines the effect of genetic sex is the mechanism that regulates the expression of sex-chromosome genes, but this is not conserved between species. In female mammals, which have two X sex chromosomes, the presence of two copies of the genes on the X chromosome is ‘compensated’ by a mechanism involving random inactivation of one X-chromosome in each cell. This is thought to be required to equalize the phenotypic effects of characteristics determined by genes on the sex chromosomes. Genes on the sex chromosomes are not conserved between birds and mammals, and until relatively recently, it was thought that avian sex chromosome genes were not subject to dosage compensation. However, we demonstrated that the levels of expression of some Z chromosome genes were equivalent in male and female chick embryos (i.e., compensated; McQueen *et al.*, 2001) and, since then, a large number of studies have confirmed and extended these initial findings. It is now generally accepted that a system of dosage compensation operates in avian tissues, but that this system is not chromosome-wide: many genes are either not compensated, or only partially compensated, and it has been proposed that dosage compensation in birds is regulated on a gene-by-gene basis (Mank and Ellegren, 2009).

Following the identification of Sry as the testis-determining gene in mammals, strenuous, but unsuccessful, efforts were made to identify an avian homologue to this master regulatory gene, and there are currently two proposed avian sex determining mechanisms that are generally considered credible. These systems are based on either a W-chromosome dominance or the dosage of a Z-chromosome gene product.

The theory of W-dominance suggests that a gene (or genes) located on the W (female-associated) chromosome would induce ovarian development and result in a female phenotype. The identification of phenotypically male ZO birds and/or phenotypically female ZZW birds would provide evidence of this mechanism and the existence of a W-chromosome ovary-determining gene. Unfortunately, there are no well-documented reports of aneuploid birds of this sort; the only ZZW birds reported were chromosomally triploid, infertile and developed ovotestes (Lin *et al.*, 1995). As such, there is currently no robust evidence for a female-dominant, W-linked sex determining gene in birds.

The alternative theory is based on the dosage of a Z-chromosome gene product, and depends on the fact that male cells carry two copies of the Z-chromosome while female cells carry only a single Z-chromosome. This hypothesis proposes that a certain amount of a specific gene product is required to trigger testis development, while lower levels lead to the development of an ovary. Here, testis development would be induced in males (ZZ) by elevated levels of expression of a Z-linked gene (or genes), while females (ZW) would fail to achieve the necessary testis-inducing expression level and ovarian development would proceed. As discussed

later, the Z-linked doublesex and mab-3 related transcription factor 1 (DMRT1) gene would be a suitable candidate for such a dosage-based system.

In mammals, while genetic elements determine the sexual fate of the developing gonads, it is generally accepted that the sexual phenotype of other tissues (secondary sexual characteristics) is principally dependent on the actions of gonadal hormones. In a recent demonstration of a major difference in the overall sex determining systems of birds and mammals, it was shown that the sexual phenotype of non-reproductive tissues in birds principally depends on the genetic make-up of the cells, i.e., whether they are genetically male or female, rather than the actions of gonadal hormones. It is interesting to note that, in mammals, hormones are not involved in primary sex-determining events, but are crucial to secondary sex determination, while in birds, hormones play a role in primary sex determination (blocking estrogen synthesis in female embryos leads to gonadal sex reversal), but have limited effects on secondary sex determination. The fact that the sexual phenotype of non-gonadal tissues is largely defined by its cellular genetic make-up rather than circulating sex steroids was demonstrated by the analysis of gynandromorph birds in which one side appeared male and one side appeared female. Studies revealed that these birds were naturally occurring chimeras composed of perfectly normal diploid male (ZZ) and female (ZW) cells, and that the side that appeared male contained predominately male cells and the side that appeared female contained predominately female cells. As both sides of these birds are exposed to the same levels of circulating hormones, the most obvious conclusion is that the different male and female phenotypes are due to the cellular composition of the tissues (Zhao *et al.*, 2010). This cell-autonomous sex identity (CASI) was confirmed by experiments where the pre-gonadal tissue from a donor embryo of one sex was transplanted to replace the pre-gonadal tissue of a host embryo of the opposite sex, and these grafted embryos re-incubated until the gonads had fully developed. In these experiments, the donor cells continued to differentiate and formed a gonad, however, this gonad was the type normally found in the donor embryo and not the type typical of the host (Zhao *et al.*, 2010). These findings were further strengthened by another study which induced the expression of aromatase in genetically male chicken embryos. The effects of the steroid hormones were secondary to the CASI of individual cells and tissues (Lambeth *et al.*, 2016).

Molecular Control of Sex Determination in Birds

DMRT1 and forkhead box L2 (FOXL2) are transcription factors which have been shown to play key roles in maintaining the adult gonadal phenotype in male and female mammals (reviewed in Huang *et al.*, 2017), and it may be that the molecular interactions and sex-specific roles of these transcription factors are conserved in birds during the embryonic phase of development. It has been proposed that both DMRT1 and FOXL2 may play key roles during primary sex determination. In keeping with this suggestion, DMRT1 and FOXL2 show sexually dimorphic expression in chick embryonic gonads at the onset of sex determination (E4.5; Ayers *et al.*, 2013), when there are a limited number of differences between males and females. Shortly afterwards (E6), there is

Fig. 1 Gonadal asymmetry and sexually dimorphic factors. (A) Light microscopy images of male and female chick embryo gonads at E10.5 of development. In males, right and left testes are of similar size, while in females the left ovary is markedly larger than the right ovary (m, mesonephros; t, testis; o, ovary). Size of bars=1 mm. (B) Summary of factors with sexually dimorphic/asymmetric distribution in developing gonads of male and female chicks ('-' indicates absence, while '+' indicates presence and relative level of individual factors). NB, While estrogen receptor is expressed in both males and females, expression is restricted to the left gonad. FOXL2, forkhead box L2; MHM, male hyper-methylated; P450, aromatase; E₂, estrogen; ER α , estrogen receptor alpha; DMRT1, doublesex and mab-3 related transcription factor 1; HEMGN, hemogen; AMH, anti-Müllerian hormone; SOX9, sex-determining region Y-box 9 protein.

a significant increase in the number of genes that differ in expression between male (656 male-biased genes) and female (347 female biased genes) embryos (see Fig. 1; Ayers *et al.*, 2015b).

In the chick embryo, the expression of DMRT1 is restricted to the gonads, PGCs and the Mullerian duct with higher levels detected in the males compared to females (Ayers *et al.*, 2015a). The timing, tissue-specificity and sexually dimorphic expression of DMRT1 makes it a good candidate for a dosage-based sex-determining gene in birds. This hypothesis is supported by experimental evidence that overexpression of DMRT1 in genetically female (ZW) chick embryos resulted in the suppression of female gonadal development. In these genetically female gonads, there were low numbers of medullary lacunae, and a thin ovarian cortex, coupled with increased expression of the male-enriched genes sex-determining region Y-box 9 protein (SOX9), Hemogen (HEMGN) and anti-Mullerian hormone (AMH), and reduced expression levels of the female-specific aromatase gene (Lambeth *et al.*, 2014). In the converse experiment, DMRT1 levels were reduced using a sh-RNAi approach in male chick gonads at E10, and this resulted in feminisation of the genetically male (ZZ) gonad. This was characterised by the development of a left-right asymmetry, an increase in the expression of the female-specific FOXL2 and aromatase genes, and a downregulation of the male-biased gene SOX9 (Smith *et al.*, 2009). These experiments suggest that DMRT1 is a significant driver of male gonadal differentiation and a regulator of many male-biased genes which are involved in sexual differentiation. Fig. 1 illustrates male and female gonadal morphology at E10.5 and list some of the molecular differences observed between the developing male and female gonads.

Currently, DMRT1 is thought to induce the expression of a number of male-biased genes following sex determination in the chicken, including HEMGN, SOX9 and AMH (see Fig. 2). Of these genes, HEMGN is the first to be expressed in the developing chick gonad, and is detectable as early as E5.5. Experiments where the expression levels of HEMGN are altered in genetically female (ZW) and male (ZZ) chicken embryos demonstrated that this gene plays a role in the male gonadal development pathway and lies upstream of SOX9 (Nakata *et al.*, 2013). The role of SOX9 in gonadal differentiation is thought to be conserved in both mammals and birds, with similar expression patterns observed in mouse, chicken, quail and duck (Fig. 2; Nakata *et al.*, 2013; Takada *et al.*, 2006a; Morais da Silva *et al.*, 1996). SOX9 is expressed in the male chicken gonad from E6.5 onwards, is responsible for induction of Sertoli cell differentiation and drives a positive feedback loop involving prostaglandin D2 synthase (PTGDS) and prostaglandin D2 (PGD2), which is also conserved in mammals (Moniot *et al.*, 2008; Wilhelm *et al.*, 2007).

In mammals, AMH expression is required to induce degeneration of the Mullerian duct in male embryos and is male-specific. In birds, although AMH is expressed in both male and female gonads, expression levels are much higher in males. In the male chick embryo, AMH is expressed from E6.5 onwards and that expression is primarily within the Sertoli cells of the seminiferous cords (Fig. 2; Oreal *et al.*, 1998). Interestingly, while AMH is directly induced by SOX9 in mammals, AMH expression in the chicken is SOX9-independent and is instead induced by SF1 (Takada *et al.*, 2006b). In knockdown-experiments in male embryos, loss of AMH led to reduced germ cell numbers in the testes, while over-expression of AMH in female embryos resulted in part-masculinised female gonads that showed increased DMRT1 expression and reduced FOXL2 expression. Both experimental scenarios

Fig. 2 Typical examples of sex-specific expression in male and female developing chick gonads. Immuno-staining of male and female chick embryo gonads on E10.5 of development for characteristic male-biased proteins SOX9 (A) and AMH (B), and female-specific aromatase protein (C). SOX9 and AMH expression in developing testes is restricted to the Sertoli cells within the sex cords bordered by laminin. Aromatase expression in the female gonads is restricted to the medulla. Laminin expression in the left female gonad defines the boundary of the cortex. There is no cortex present in the much smaller right female gonad, however, this organ is still steroidogenically active as demonstrated by aromatase expression. SOX9, sex-determining region Y-box 9 protein; LAM, laminin; AROM, P450 aromatase. Size of bars=100 μ m.

resulted in smaller gonads (Lambeth *et al.*, 2015, 2016). AMH has been shown to inhibit aromatase expression and the steroidogenic capacity was affected in both male and female gonads overexpressing AMH (Lambeth *et al.*, 2016; Bruggeman *et al.*, 2002). These studies demonstrate that AMH is involved in gonadal development in both sexes and it can partially induce testicular development in a genetically female (ZW) embryo.

FOXL2 is expressed in the female chick gonad at an earlier stage (E4.5) than other female-biased genes, and is often considered as the female counterpart of DMRT1, in the sense that it is thought to regulate ovarian development (Govoroun *et al.*, 2004). A sharp increase in the levels of FOXL2 in the gonad is observed at the beginning of sex determination in the female chicken, followed closely by an increase in the levels of aromatase (Fig. 2; Govoroun *et al.*, 2004). FOXL2 has been shown to regulate aromatase expression in the goat (Pannetier *et al.*, 2006) and it was thought to play a similar role in birds, however, it has recently been proposed that SF1 regulates expression of aromatase in the female chick gonad (Wang and Gong, 2017). During gonadal differentiation, FOXL2 is highly expressed in the female compared to male gonads (Govoroun *et al.*, 2004). Although there are no reports of direct FOXL2 manipulation in the chicken, FOXL2 has been shown to be essential for granulosa cell differentiation, oocyte differentiation and steroidogenesis in the mouse ovary, and ablation of FOXL2 in adult mice led to masculinisation, suggesting that its role in the adult mouse is to maintain sexual phenotype (Uda *et al.*, 2004; Uhlenhaut *et al.*, 2009).

In mammals, there is evidence for an alternative ovarian differentiation pathway that is independent of FOXL2. This pathway is the wingless-type MMTV integration site family (Wnt) canonical pathway, which includes r-spondin 1 (RSPO1) and wingless-type MMTV integration site family, member 4 (WNT4) and activates beta catenin (CATNNB; Tevosian, 2013). In the chicken, although this pathway is not well-characterised, elevated levels of RSPO1 are seen in female chick gonads from E4.5 onwards and coincide with both FOXL2 and aromatase expression (Fig. 2). The RSPO1 protein is localised to the cortex of the developing ovary and expression of RSPO1 was reduced by inhibiting aromatase expression, suggesting that estrogens affect RSPO1 similarly to FOXL2 in the chicken (Smith *et al.*, 2008). However, in goats, FOXL2 and RSPO1 are expressed in different ovarian compartments

Fig. 3 Proposed scheme for regulation of sex determination in birds. Following fertilisation of Z-bearing or W-bearing oocyte, the major factor in defining the adult sexual phenotype, is the inherent sex identity (CASI) of individual cells and tissues. Male genital ridges develop into testes because they are composed of male (ZZ) cells, while female genital ridges initiate ovarian development because they are composed of female cells. Broken arrows indicate that gonadal factors have only a limited influence on the sexual phenotype of the adult bird. Factors regulating the differentiation of the genital ridge into either a testis or an ovary, are illustrated (see text for details). With minor exceptions, the majority of these factors are conserved between gonadal development in birds and mammals. A notable exception is estrogen (E₂) which plays a major role in ovarian development in birds. E4, embryonic day 4; DMRT1, doublesex and mab-3 related transcription factor 1; HEMGN, hemogen; SF1, steroidogenic factor 1; AMH, anti-Müllerian hormone; PGD2, prostaglandin D2; PTGDS, prostaglandin D2 synthase; SOX9, sex-determining region Y-box 9 protein; FOXL2, forkhead box L2; P450, aromatase; E₂, estrogen; ERα, estrogen receptor alpha; WNT4, wingless-type MMTV integration site family, member 4; CATNNB, beta catenin; RSPO1, r-spondin 1.

(FOXL2 in the medulla, RSPO1 in the cortex) and are therefore members of different pathways. Fig. 3 summarises our current understanding of the sex determination process in birds.

In contrast to mammals, chicken embryonic gonads are sensitive to sex steroids during development (reviewed in Bruggeman *et al.*, 2002), and both female gonads have the capacity to produce estrogen at the time of sex differentiation. The left gonad of both male and female embryos express estrogen receptor alpha (ER α) between E7 and E10 and are capable of responding to estrogen if this steroid is present. Gonadal sex reversal is possible through sex steroid manipulation in both sexes, but the resulting phenotypes are variable and mostly reversible (Bruggeman *et al.*, 2002), reinforcing the concept of cell autonomous sex identity. Inhibiting estrogen production in genetically female embryos leads to a decrease in FOXL2 levels, suggesting that FOXL2 can respond to estrogen abundance, putatively through a feedback loop (Hudson *et al.*, 2005). Steroid feminisation of genetically male embryos leads to gonadal asymmetry and decreased expression of male-biased genes, including DMRT1 (Lambeth *et al.*, 2013).

Another interesting female-biased, Z-linked region is male hyper-methylated (MHM), which contains multiple repeats of a long, non-coding RNA (lncRNA) that accumulates in the region of the DMRT1 promoter in ZW females. Hypothetically, MHM may be involved in the inhibition of DMRT1 in females, in a similar manner to X-inactive specific transcript (XIST) X-chromosome inactivation in mammals. Overexpression of MHM in male embryos did not induce sex reversal, however it affected male gonad development and led to a down-regulation of DMRT1 (Roeszler *et al.*, 2012). Further research suggests that MHM is associated with sex determination in both sexes (Yang *et al.*, 2016), but the exact association between MHM and the molecular pathways underlying sex determination in birds is not clear.

Conclusions

In summary, the sex determination mechanism in birds differs to that seen in mammals in that it is not obviously dependent on a single master regulatory gene and there is also a strong cell autonomous element. In mammals, primary and secondary sex determination are inextricably linked: genetic sex determines the type of gonad formed and this in turn determines the adult sexual phenotype. In birds, primary and secondary sex determination are less closely linked: genetic sex determines the type of gonad formed but the adult sexual phenotype is defined by cellular sex identity rather than gonadal hormone action. Despite this crucial difference, many aspects of the morphology and molecular control of sexual development is conserved in both classes.

At the morphological level, avian and mammalian gonadogenesis differ in terms of a left-right asymmetry and in the source of the gonadal cell precursors: avian PGCs migrate through the circulation to reach the developing gonad and avian Sertoli cells originate in the nephrogenic mesenchyme. At the molecular level, evidence suggests that DMRT1 is essential for testis development, and while estrogen influences gonadal fate, non-reproductive tissues are largely defined by the genetic make-up of the constituent cells.

Future investigation of the sex determining mechanisms of birds should delve into the complex regulatory interactions between the components of the pathways and clarify the influence of important genes such as DMRT1 and FOXL2 in the process. Advances in gene editing technology allow easy and cost-effective generation of transgenic organisms, which will undoubtedly assist with further characterisation of molecular components of the sex determining pathways of different species.

Glossary

Anterior pituitary The glandular, anterior lobe of the pituitary gland.

Bidirectional sex change A sequential hermaphrodite that can change from female to male, and male to female.

DNA methylation Physical changes to DNA that change gene expression without changing the underlying DNA sequence.

Epigenetic modifications Physical changes to DNA that change gene expression without changing the underlying DNA sequence.

Genome The entire set of genes of an individual.

Gonochoeristic An individual that functions as one sex its entire life (does not undergo sex change).

Lifetime reproductive success The total number of offspring an individual produces over its entire lifespan.

Monogamy One male and one female mate.

Ovotestis A bisexual gonad containing both ovarian and testicular tissue.

Polygyny One male mates with more than one female.

Protandry A sequential hermaphrodite that changes from male to female.

Protogyny A sequential hermaphrodite that changes from female to male.

Sequential hermaphrodite An individual that functions as both a female and male at different time points in their life.

Steroidogenesis The biological synthesis of steroid hormones.

Teleost A taxonomic grouping of fishes that make up approximately 96% of all fish, the ray-finned fishes.

Temperature dependent sex reversal An interaction between genetic sex determination and temperature sex determination in which the temperature experienced during development can reverse the chromosomal sex.

Tetrapod A taxonomic grouping of vertebrates, the four-limbed vertebrates.

Transcriptome The set of RNA molecules present in a cell or population of cells.

What is Sex Change?

The majority of organisms develop as one sex and remain that sex throughout their life. However, a range of plant and animal species are sequentially hermaphroditic, beginning life as one sex and changing to the opposite sex at a later point. The change associated with sequential hermaphroditism is commonly known as sex change and occurs as a natural part of the life cycle of many species. This is in contrast to artificially induced feminization or masculinization, e.g., by environmental pollutants. Teleost (bony) fishes are the only vertebrate lineage to contain species that undergo sex change as part of their natural life cycle. Sex change is widespread in teleosts, occurring in at least 27 families, spread across nine orders. Teleosts display three patterns of sequential hermaphroditism: protandry (male to female), protogyny (female to male), and bidirectional (serial sex change in both directions).

Why Change Sex?

The main theory explaining why sex change is beneficial is the size advantage model. This model states that sex change is adaptive when the reproductive success of each sex differs depending on the size of an individual, i.e., an individual has greater reproductive success as one sex when small but the opposite sex when large. The timing of sex change should occur to maximize the lifetime reproductive success of an individual (combined male and female lifetime reproductive success). The differential reproductive success of each sex is associated with a species' mating system and social structure. Therefore, the pattern and timing of sex change also depends on the species' mating system and social structure.

Protogyny

Protogynous (female to male) sex change is favored in a polygynous mating system, in which one or a few large males monopolize matings with females. In this system, males aggressively defend a mating territory for courtship with females. Therefore, male reproductive success strongly depends on body size, with smaller males being at a reproductive disadvantage and large males having higher reproductive success due to the ability to defend a mating territory and mate with multiple females. Reproduction as a female when small, followed by sex change to reproduce as a male when large, will increase lifetime reproductive success of an individual

despite the physiological cost of sex change. Highly social polygynous wrasses, such as the bluehead wrasse (*Thalassoma bifasciatum*) commonly display protogyny. In this species, dominant males defend spawning sites for courtship with females. Loss of a dominant male results in protogynous sex change of a large female.

Protandry

When mating is random, or is monogamous (one male mates with one female), protandry (male to female sex change) is favored. In these systems, female fertility increases more rapidly with size than male fertility and larger females usually have a higher reproductive success than males of the same size. Thus, it is beneficial for individuals to reproduce as males while small, and as females when older and larger. For example, monogamous clownfish (*Amphiprion* and *Premnas* sp.) show protandrous sex change. The small social group of clownfish consists of a single mating pair; a dominant female and small male, as well as several smaller, subordinate non-breeders. Loss of the dominant female results in protandrous sex change of the small male, and maturation of one of the subordinate non-breeders to replace the breeding male.

Bidirectional Sex Change

Bidirectional sex change allows an individual to mate with any other adult it encounters. Thus, bidirectional sex change is adaptive for species that occupy a patchy or highly heterogeneous habitat where there is a low probability of finding a new mate and searching for a new partner involves a high predation risk. For example, many monogamous coral gobies (e.g., *Gobiodon* and *Paragobiodon* sp.) are bidirectional sex changers. Coral gobies have limited mating opportunities, and predation risk is high when travelling between the spatially isolated coral colonies they inhabit. Bidirectional sex change allows any two fish to form a heterosexual breeding pair, increasing mating opportunities and decreasing the time and risk of finding a new partner.

What Happens During Sex Change?

Sex change consists of three stages; behavioral, gonadal and morphological sex change. These stages of sex change are clearly illustrated in the bluehead wrasse, a well-studied model of protogynous sex change. Within minutes to hours of removing a dominant male, the transitioning female starts showing male-specific behaviors such as aggression and courtship. Gonadal restructuring then takes place, in which the ovary regresses and is replaced by a testis in as little as eight to ten days. External morphological changes such as change in body shape and color are the last to be completed. In the bluehead wrasse, it can take up to three weeks for males to develop full coloration (Fig. 1).

Among sequentially hermaphroditic lineages there are differences in how gonadal sex change occurs. Some species show complete restructuring of the gonad. For example, in protogynous wrasses the ovary contains no testicular tissues prior to sex change, and the sex-changed male testis contains no ovarian tissue, with only a remnant ovarian lumen. As no male tissues are identifiable prior to sex change, it is unknown where the male cells originate from. In protogynous wrasses, it is likely that germ line cells found on the periphery of the ovarian lamellae are sources for testicular development. However, it has not been definitively established whether these cells are a dormant, but sexually differentiated population of germ cells (i.e. oogonia and spermatogonia co-existing in the gonad), or if they are primordial germ cells that are sexually bipotent and undifferentiated.

In other sequential hermaphrodites, both ovarian and testicular tissue is present in the gonad simultaneously, which is known as a bisexual gonad or ovotestis. Protandrous black porgy (*Acanthopagrus schlegelii*) are functionally male for the first two years of life, possessing an ovotestis dominated by testicular tissue that is separated by connective tissue from a few oogonia and primary oocytes. In the non-spawning season, before their third year of life, primary oocytes develop and ovarian tissue begins to dominate

Fig. 1 Timeline of behavioral, gonadal and morphological changes across protogynous sex change in the bluehead wrasse. Copyright 2016, Wiley Periodicals, Inc.

the gonad as testicular tissue regresses. By three years of age, all fish are functionally female and the ovotestis is completely replaced by ovarian tissue. Bidirectionally sex changing gobies have an ovotestis throughout life. This allows rapid and serial switching of gonadal fate.

The time taken to complete sex change varies greatly between species, from as little as days to weeks in some species, to months in others. In temperate fishes that breed seasonally, sex change only occurs outside of the breeding season and occurs over a longer time-frame (months) than in tropical fishes that breed year-round and can change sex more rapidly and throughout the year.

How is Sex Change Regulated?

Fish use a variety of environmental or physiological cues to trigger sex change. One of the most common cues is the immediate social environment, e.g., an individual's size relative to others in the social group, the local sex ratio in a social group, the local density of fish in a social group, and the presence or absence of a dominant individual. Sex change may also be cued by reaching a critical age or size. For example, black porgy change sex from male to female between their second and third breeding seasons.

It is not fully understood how environmental cues are translated into a rapid behavioral response, and the ensuing physiological response that is sex change. However, it appears that neuroendocrine systems are key signaling pathways in controlling sex change, communicating information between the brain and gonad. There is likely cross-talk between multiple neuroendocrine systems to coordinate physiological changes at a whole-body level.

Regulation of Behavioral Sex Change

Neurochemical changes in the brain appear to drive behavioral sex change. However, how these neurochemical changes transduce the environmental cues into a rapid behavioral transformation is still poorly understood. Arginine vasotocin (AVT), and to a smaller extent isotocin, have been the focus of research for behavioral sex change. These neuropeptides are the teleost homologues of mammalian vasopressin and oxytocin, respectively. In mammals and other tetrapods, vasopressin mediates male social behaviors, such as aggression and territoriality, a role which appears to be conserved for AVT in teleosts. Experiments in the protogynous blue-head wrasse demonstrate that AVT likely plays a critical role in stimulating behavioral sex change. Oxytocin is well known for its role in female sociosexual behaviors in mammals, including parturition, lactation, maternal attachment, and pair bonding. In fishes, isotocin has also been associated with sociosexual behaviors, and gene expression and protein abundance of isotocin in the brain have been shown to change across protogynous sex change. However, opposing trends in isotocin expression are reported in different species, and the role of isotocin in sex change is not yet well understood.

Changes in other neurochemicals during early sex change may orchestrate behavioral sex change, and are also known to regulate the hypothalamic-pituitary-gonadal (HPG) axis that controls steroidogenesis in the gonad, thereby possibly acting as a link between behavioral and gonadal sex change. Norepinephrine appears to stimulate protogynous sex change, while dopamine and serotonin have inhibitory effects on protogynous sex change. Kisspeptin is well known for its role in stimulating the HPG axis, and it appears to also be involved in sex change, however its precise role remains unclear (Fig. 2).

Regulation of Gonadal Sex Change

Hypothalamic-Pituitary-Gonadal Axis

The HPG axis is a major signaling pathway controlling gonadal sex change in fish. Unlike other vertebrates, gonadotropin releasing hormone (GnRH) neurons located in the preoptic area of the hypothalamus directly innervate the anterior pituitary in fish. In the anterior pituitary, GnRH is released and stimulates the synthesis and release of the gonadotropins luteinizing hormone and follicle stimulating hormone into circulation. Gonadotropins act through their receptors in the gonad, either on follicle cells in the ovary or leydig cells in the testis, to regulate the production of sex hormones (including estrogens and androgens) (Fig. 2).

In most teleost fish, the main estrogen and androgen are 17 β -estradiol (E2) and 11-ketotestosterone (11-KT), respectively. The balance between these two sex steroids controls gonadal fate, with E2 promoting ovarian function, and 11-KT testicular function. Testosterone (T) acts as a prohormone in fish and is converted to E2 via the enzyme aromatase, and to 11-KT via the enzymes 11 β -hydroxylase (11 β H) and 11 β -hydroxysteroid dehydrogenase 2 (11 β HSD2) (Fig. 2). Therefore, relative functioning of these pathways in the gonad determines the balance of E2 and 11-KT, and subsequently gonadal fate.

Dramatic shifts in E2 and 11-KT blood serum levels occur across sex change in fish. In protogynous sex change, a rapid decrease in E2 is followed by a steady increase in 11-KT (Fig. 3). Treatment of adult females with either an aromatase inhibitor (AI) or 11-KT, can decrease E2 production and increase 11-KT plasma levels to induce complete sex change. It is thought that a decrease in E2 levels below a threshold will result in oocytes being unable to survive, while increasing 11-KT levels may accelerate ovarian atresia while also initiating proliferation of spermatogonia. The opposite pattern is seen in protandrous sex change: 11-KT levels drop before there is an increase in E2 production (Fig. 3). Similarly, AI administration to adult males can suppress natural sex change in protandrous species.

Fig. 2 Diagram of the HPG and HPI axes depicting the neuroendocrine regulation of steroidogenesis in fish, as well as the interaction of cortisol with the HPG axis. 5-HT, serotonin, ACTH, adrenocorticotropic hormone, CRH, corticotropin releasing hormone, DA, dopamine, FSH, follicle stimulating hormone, FSHR, follicle stimulating hormone receptor, GnRH, gonadotropin releasing hormone, kiss, kisspeptin, LH, luteinizing hormone, LHR, luteinizing hormone receptor, MC2R, melanocortin 2 receptor, NE, norepinephrine, 11 β H, 11 β -hydroxylase, 11 β HSD2, 11 β -hydroxysteroid dehydrogenase type 2. Figure adapted from Liu, H., Todd, E.V., Lokman, M.P., *et al.*, 2016. Sexual plasticity: A fishy tale. *Molecular Reproduction and Development* 84, 171–194.

Fig. 3 Hormonal changes across protogynous (A) and protandrous sex change (B). Reprinted with permission from Todd, E., Liu, H., Muncaster, S., Gemmell, N., 2016. Bending genders: The biology of natural sex change in fish. *Sexual Development* 10, 229. Copyright 2016, S. Karger AG, Basel.

The importance of the HPG axis in controlling the E2–11-KT balance, and thus gonadal fate, has been demonstrated through several manipulative studies. For example, administration of GnRH and gonadotropins (or derivatives of these) in protogynous species results in a drop in E2 levels and an increase in 11-KT, inducing gonadal sex change. Thus, changes in gonadal sex steroid levels and subsequently gonadal sex change, can be controlled by the brain via the HPG axis.

Hypothalamic-Pituitary-Interrenal Axis

In fish, the hypothalamic-pituitary-interrenal (HPI) axis mediates the stress response and has also, more recently, been implicated in sex change. Corticotropin releasing hormone is secreted from the hypothalamus, stimulating the anterior pituitary to release adrenocorticotrophic hormone (ACTH) into the circulation. ACTH acts on melanocortin 2 receptors present on interrenal cells (dispersed throughout the head kidney and homologous to the mammalian adrenal glands), activating the biosynthesis and release of cortisol, the primary stress hormone in vertebrates (Fig. 2).

The HPI axis may interact with the HPG axis to promote sex change in fish. In a range of gonochoristic (non sex-changing) fish species, environmental stressors such as elevated temperature have been found to increase cortisol levels and cause gonadal masculinization. In sequential hermaphrodites, a transient peak in plasma cortisol levels has been observed during both protogynous and protandrous sex change (Fig. 3), and long-term cortisol treatment was shown to promote protogynous sex change in the three-spot wrasse (*Halichoeres trimaculatus*). Cortisol is thought to promote sex change via its actions on aromatase and 11-KT. Cortisol inhibits aromatase expression, halting the conversion of T to E2 (Fig. 2) and decreasing E2 production, which increases the availability of T to be converted into 11-KT. Furthermore, the expression of 11 β HSD2, the enzyme which catalyzes the production of 11-KT (this enzyme also catalyzes cortisol to the inactive form cortisone), is stimulated by cortisol, which may further increase 11-KT production (Fig. 2). Thus, the cortisol pathway may act as an interface between the HPI and HPG axes, tipping the E2–11-KT balance to promote sex change.

Molecular Regulation of Sex Change

Genetic Regulation

At a molecular level, primary sex-determination in the early embryo is no longer considered a permanent switch. Rather, there is a battle for dominance between female and male regulatory gene networks. Antagonistic feminizing (e.g., *foxl2*, *wnt4*, *cyp19a1a*) and masculinizing (e.g., *dmrt1*, *amh*, *sox9*) gene networks promote ovarian and testicular development respectively, while actively suppressing expression of the opposing sexual network. Activation of one sex-specific network, but also continual suppression of the opposing sex differentiation network, is required for maintenance of gonadal fate. This means that sexual fate can be manipulated by factors that interrupt the dominant sexual network and allow the opposite sexual network to overtake. In sex changing fish, it appears that this system has been exploited, with factors that interrupt the dominant sexual network having come under control of environmental cues.

Research shows that in both protandrous and protogynous fishes, a shift occurs from expression of one sex-specific gene network to the other. In the protandrous black porgy, males show high expression levels of male-related genes in the testis (e.g., *dmrt1*, *amh*, *amhr2*) and a decline in male-related gene expression is associated with testis regression. As protandrous sex change continues and the ovary develops, the gene expression profile becomes increasingly feminized (e.g., *cyp19a1a*, *foxl2*, *wnt4*) (Fig. 4). An opposite pattern is observed in the protogynous bluehead wrasse. Whole-transcriptome expression profiling in this species revealed a gradual decline in expression of female-pathway genes in the gonad (e.g., *dax1*, *cyp19a1a*, *figla*, *gdf9*, *hsd7b1*, and *hsd11b3*), followed by increased expression of male-related genes (e.g., *dmrt1*, *amh*, *amhr2*, *sox9a/b*, and *gsdf*) (Fig. 4).

The genetic mechanism that triggers this shift in sex-specific gene expression in sequentially hermaphroditic fish has yet to be determined in any species. However, a key component of the genetic mechanism that initiates protogynous sex change is the gene *cyp19a1a*, coding for the enzyme gonadal aromatase that converts T into E2. *Cyp19a1a* is currently the only gene shown to rapidly and completely shut down early in protogynous sex change, when the first signs of ovarian atresia are observed (Fig. 4). This rapid downregulation of *cyp19a1a* parallels the sharp decline in plasma E2 levels that occurs early in protogynous sex change (Fig. 3). Manipulative studies have shown that treatment of protogynous fish with an aromatase inhibitor decreases E2 levels and

Fig. 4 Changes in sex-specific gene expression across protogynous (A) and protandrous sex change (B); a shift occurs from one sexual network to the opposing sexual network. Reprinted with permission from Todd, E., Liu, H., Muncaster, S., Gemmell, N., 2016. Bending genders: The biology of natural sex change in fish. Sexual Development 10, 229. Copyright 2016, S. Karger AG, Basel.

induces complete sex change. Thus, it appears that downregulation of *cyp19a1a* is a switch that initiates gonadal sex change in protogynous fish. Therefore, upstream factors that suppress *cyp19a1a* expression are potential components of a trigger mechanism.

Epigenetic Regulation

Epigenetic modifications, e.g., DNA methylation and histone acetylation, are physical changes to DNA that alter gene expression without changing the underlying genetic code. Such modifications affect gene expression by altering gene availability to transcription, and typically inhibit (via DNA methylation), or promote (via histone acetylation) transcription. These modifications occur naturally and are critical to development. Epigenetic machinery can respond to environmental influences, and so may be a means by which environmental cues are translated into changes in gene expression to elicit a phenotypic response.

As sequential hermaphroditism in many fishes relies on environmental cues, namely social cues, epigenetic modification of sex-pathway genes is a potential mechanism through which gene expression could be regulated, and sex change initiated and maintained. DNA methylation has been demonstrated as an upstream mechanism regulating *cyp19a1a* expression. In gonochoristic (unisexual) fish, *cyp19a1a* expression is higher in the ovary than the testis, and DNA methylation levels of the *cyp19a1a* promoter region are lower in the ovary than the testis. This suggests that DNA methylation of the *cyp19a1a* promoter region may suppress expression of *cyp19a1a* in the testis. DNA methylation changes to *cyp19a1a* may regulate temperature dependent sex reversal in fish, as well as sex change in sequentially hermaphroditic fish. In genetic females, high temperatures have been found to increase DNA methylation of the *cyp19a1a* promoter region, decrease *cyp19a1a* expression, and masculinize the female ovary. In protogynous species, DNA methylation levels of the *cyp19a1a* promoter region have been found to increase during sex change as *cyp19a1a* expression decreases. Thus, DNA methylation is an upstream factor that suppresses *cyp19a1a* expression and is a potential component of a trigger mechanism of sex change.

As well as DNA methylation influencing *cyp19a1a* expression, it is likely that DNA methylation occurs throughout the genome to regulate the shift that occurs across sex change from expression of one sex-specific gene network to the opposing gene network. In half-smooth tongue sole (*Cynoglossus semilaevis*), a species displaying temperature dependent sex reversal, sex pathway genes were differentially methylated depending on their level of expression in an ovary or testis, for example, female-pathway genes that were highly expressed in the ovary showed low levels of DNA methylation, while in the testis these female-pathway genes showed lower expression levels and higher levels of DNA methylation. The overall methylation pattern of pseudo-male (sex reversed females), and male testes was very similar suggesting that female genome-wide methylation patterns are altered to match those of normal males after sex change. Thus, temperature dependent sex reversal during development likely involves DNA methylation throughout the genome regulating the expression of one or the other sex-specific pathway. Implantation of protogynous fish with a DNA methylation inhibitor halted, or reversed, the protogynous sex change process, suggesting DNA methylation may function similarly in sequentially hermaphroditic fish that change sex in adulthood.

Sexual Dimorphism: Difference Between Males and Females

In insects, males and females have distinct structures, known as sexual dimorphism. Moreover, certain insect species remarkably exhibit this dimorphism. For instance, in stag beetles, only males have outstanding mandibles (Fig. 1(a)), whereas in scale insects, both males and females have distinct structures as well as sizes (Fig. 1(b)). Further, butterflies show differences in wing color between males and females (Fig. 1(c)). Hence, males and females have fundamentally distinct structures and functions in sexual behavior and reproduction. How do such sexual differences arise?

Sex determination refers to the developmental processes that lead to differentiation between males or females. Spontaneous occurrence of gynandromorphism (i.e., chimeric individuals of male and female tissues; See “gynandromorph and intersex”), albeit in low frequency, is considered as the ground for genetic sex determination during early embryogenesis. Moreover, it cannot be altered during later development (Narita *et al.*, 2010). Particularly, each cell comprising the insect body determines its sex independently (cell-autonomous sex determination) and is not affected by diffusible substances like sex hormones.

Gynandromorph and Intersex

A gynandromorph (synonymous with a sexual mosaic) is a genetically chimeric individual, whereas an intersex is a genetically uniform individual (Goldschmidt, 1934; Laugé, 1985; Fig. 2). Double fertilization of a binucleate egg, loss of a sex chromosome, or upregulation/downregulation of sex determining genes is considered developmental mechanisms for gynandromorph and intersex occurrence (Narita *et al.*, 2010).

Sex Chromosomes and Sex Determination

In most insects, a chromosome pair (sex chromosomes) is distinctive between males and females. For example, in some flies and beetles, males are heterogametic (XY), whereas females are homogametic (XX), which is reversed in the case of butterflies and moths (i.e., ZZ males and WZ females). Moreover, in certain species, males have only one sex chromosome (X) without any pairing chromosome and are designated as X0, whereas females are XX. Conversely, in certain moths, females are Z0 and males are ZZ. Mendelian inheritance of sex chromosomes ensures 1:1 sex ratio in species having sex chromosomes (see “meiotic drive” for exceptions).

However, certain insects like wasps and bees, belonging to the family Hymenoptera, lack sex chromosomes. Instead, females have a genome sized twice as that of males, the reproductive system called haplodiploid, wherein unfertilized eggs develop as haploid males (n) and fertilized eggs develop as diploid females ($2n$). In some parasitic wasps like *Nasonia vitripennis*, which lay eggs in fly hosts wherein a limited number of wasps survive, females can control the proportion of eggs that get fertilized with the male sperm, thereby achieving most advantageous sex ratios that are theoretically deduced (cf. local mate competition).

Meiotic Drive

Meiotic drive is a violation of the Mendelian inheritance that results in a skewed ratio of functional X-bearing and Y-bearing sperms or W-bearing and Z-bearing eggs. In certain flies like *Drosophila*, some X chromosomes favor Y-bearing sperm inactivation, leading to all or nearly all females. Such X chromosomes are categorized as one of the selfish genetic elements that have a potential to spread in the population at the expense of the rest of the genome. Interestingly, autosomal and Y-linked suppressors against these X drive have been discovered, and some of them have reached near fixation in certain populations. Fixation of both drivers and suppressors results in a normal 1:1 sex ratio.

Molecular Mechanisms of Sex Determination

In insects, sex determination is governed by a cascade of several genes that can be well understood in a model insect i.e., the fruit fly *Drosophila melanogaster* (Fig. 3) (Sánchez, 2008). In *D. melanogaster*, the Y chromosome does not participate in sex determination, instead, certain specific genes located on the X chromosome activate the master sex determining gene *Sex-lethal* (*Sxl*) at a very early stage of embryogenesis. *Sxl* has two distinct “early” and “late” promoter regions. X-linked genes activate the “early” promoter in a dose-dependent manner. Further, *Sxl* turns ON in XX females and OFF in XY males. The positive regulatory function then allows continuous *Sxl* expression even without X chromosome signals. After the blastoderm stage, the “late” *Sxl* promoter begins to function in both sexes, and the *Sxl* mRNA undergoes splicing in distinctive manners in males and females. The male transcript gives rise to truncated, nonfunctional *Sxl* proteins (SXL^M). Functional *Sxl* proteins (SXL^F), are produced only in females and affect the splicing of another gene, *transformer* (*tra*), leading to a functional protein being produced (otherwise, *tra* produces a truncated nonfunctional protein TRA^M in males). The functional TRA protein (TRA^F) then affects another gene *doublesex* (*dsx*), which is to be spliced in specific manner to produce dsx^F (female-specific splicing product). Otherwise, *dsx* is spliced to produce dsx^M (male-specific splicing product). Their protein products (DSX^F and DSX^M) are both functional and induce somatic sexual differentiation. Behavioral differences among males and females such as mating behavior are governed by sex differences in the nervous systems. The neural sex differences in *Drosophila* are generated under the hierarchical control of two sex determining genes, *fruitless* (*fru*) and *dsx*. *dsx* also plays a key role in sex determination in soma, whereas *fru* exerts its sex determining function only in neural cells (Yamamoto and Koganezawa, 2013).

Fig. 3 Somatic sex determining gene cascade in *Drosophila melanogaster*.

Interestingly, the molecular mechanisms of sex determination in *D. melanogaster* cannot be simply extrapolated to other insects. Even in other flies (Diptera), *Sxl* does not play any role in somatic sex determination. Recently, it has become evident that the sex determining mechanism evolution is far more dynamic than that anticipated (Gempe and Beye, 2011). In insects, *dsx* is the only gene that is widely conserved structurally as well as functionally. Homologs of *dsx* (particularly, those sharing a DNA-binding motif called DM domain) can also be found in the soil-dwelling nematode *Caenorhabditis elegans* (*mab-3*) in mammals and birds (DMRT1). The above homolog functions as a sex determining gene for somatic sexual differentiation as well as germline differentiation. Conversely, *tra* is conserved between Diptera and Hymenoptera, but not in Lepidoptera. Further, *Sxl* is structurally conserved widely among insects and functions as a sex determiner only among closely related species of *D. melanogaster*. (Confusingly, *Sxl* functions as a sex determiner in *C. elegans* despite the long phylogenetic distance between the organisms.)

Furthermore, in the silkworm *Bombyx mori*, the presence of W chromosome has been recognized as important for female sex determination by the presence of variety of strains with chromosome aberrations. Critically, a recent molecular study revealed that a small RNA, particularly, a piwi-interacting RNA (piRNA) called *feminizer* (*fem*) is located on the W chromosome. Here, it acted as a female determiner by silencing the Z chromosome-located male determining gene *Masculinizer* (*Masc*) through the ping-pong cycle (Kiuchi et al., 2014). Independently, a P-element somatic inhibitor, expressed in both sexes in combination with sex-specifically spliced mRNA-binding protein (IMP), was shown to regulate *dsx* sex-specific splicing in *B. mori* (Suzuki et al., 2008, 2010).

In honeybees, which lack sex chromosomes, heterozygosity in *csd* locus leads to female sex determination (*complementary sex determination*). Therefore, haploid individuals are males whereas diploid individuals are usually females; however, under inbreeding conditions, diploid males appear as homozygous for *csd*. It is known that *csd* is homologous to *tra*, wherein *csd* regulates *dsx* splicing (Beye et al., 2003). More perplexingly, complementary sex determination is not the only sex determination mechanism in Hymenoptera. In the parasitic wasp *Nasonia vitripennis*, *tra* zygotic activity is autoregulated and dependent on a combination of maternal provisions of *tra* mRNA and a paternal genome set (Verhulst et al., 2010).

Is *dsx* A Master-Switch for Sex Determination?

dsx is widely conserved among insects as well as vertebrates (Fig. 3). Previously, *dsx* was regarded as the final master-switch gene in the sex determination cascade of all insect species. However, it was later found that *dsx* is not expressed in all cells, but rather forms an expression pattern mosaic in developing and adult individuals. Furthermore, homeotic genes (HOX genes) were noticed to regulate *dsx* expression. Growing evidence suggested that *dsx* regulation is based on sex-specific morphological differences (Fig. 4). Further, *dsx* is ordered to present this information in the case where sexual identity is required. Thus, *dsx* is not the final master-switch in the sex determination cascade, but is rather the central switch at the interface between sex determination and sexual differentiation (Verhulst and van de Zande, 2015).

Fig. 4 *Doublesex (dsx)* as the interface of sex determination and sexual differentiation. Reproduced from Verhulst, E.C., van de Zande, L., 2015. Double nexus – Doublesex is the connecting element in sex determination. *Briefings in Functional Genomics* 14, 396–406.

Microorganisms as Sex Determiners

In insects, cytoplasmic elements (such as mitochondria and various microorganisms) are always transmitted from mothers to offspring. Therefore, a female-biased sex ratio is obviously advantageous for cytoplasmic elements (Burt and Trivers, 2006). Interestingly, some cytoplasmic elements could skew the sex ratio toward females in certain arthropod species (Kageyama *et al.*, 2012). In the woodlouse, *Armadillidium vulgare* (wherein females constitute WZ and males have ZZ sex chromosome), the presence of a maternally inherited microorganism (*Wolbachia* bacterium) results in the feminization of genetically male individuals (ZZ) into functional females. Interestingly, W chromosomes are lost in some *A. vulgare* populations (i.e., all individuals being ZZ) and the presence or absence of *Wolbachia* determines the sex. In such populations, *A. vulgare* could be regarded as an organism that lacks sex chromosomes (i.e., Z chromosomes behave like autosomes). In certain insects like *Drosophila*, ladybird beetles, butterflies, moths, planthoppers and lacewings, *Wolbachia* or other bacteria that reside in the insect body only kill males during embryonic or early larval development, leading to all female offsprings. In the moth *Ostrinia scapularis*, *Wolbachia*-infected ZZ males die during

embryonic development. Partial elimination of *Wolbachia* in mothers leads to the production of intersex individuals (genetically purely male, ZZ) comprising male-like as well as female-like tissues (Fig. 2(b)). Further, *Wolbachia* was considered to have a female determining function as the *dsx* splicing pattern for dying ZZ individuals was all female type. Z-linked gene expression levels revealed that the dosage compensation improperly functioned because of the sex alterations imposed by the bacterium (see below).

Several solitary wasp strains or species asexually reproduce, i.e., eggs laid by virgin females hatch and develop to all females. The lack of males in a considerable number of species, but not all, is caused by cytoplasmic bacteria such as *Wolbachia* and *Cardinium* (Rabeling and Kronauer, 2013).

Dosage Compensation

Not all sex chromosome genes (particularly, X and Z) have sex-specific functions. Particularly, equal gene product amounts are required between males and females for many sex chromosome genes. Thus, although chromosome numbers are different between males and females, X- or Z-linked gene products should be regulated to be comparable between males and females. Such regulatory mechanisms, called dosage compensation, widely exist in animals but with variable manners between the taxa. In *Drosophila*, single male X chromosome transcription increases by two-fold, thereby adjusting it with that of females (Fig. 5(a)). In mammals including humans and mice, the expression of one of the X chromosomes in an XX female is eliminated, so that both males and females express only one X chromosome. Either the maternal or paternal X chromosome is randomly inactivated in every cell of the female body. Hence, the above process is often called random X inactivation (Fig. 5(b)). The nematode *C. elegans* adopts an alternative way to equalize X-linked gene expression among males and females. In *C. elegans*, worms with two X chromosomes (XX) develop as hermaphrodites, whereas those with only one X chromosome (XO) develop as males. In this system, gene expression on both X chromosomes of the XX worms is downregulated by half, thereby equalizing the X-linked gene expression to that of XO males (Fig. 5(c)).

In *Drosophila*, the MSL (male-specific lethal) ribonucleoprotein complex comprising five proteins [*maleless* (*mle*), the *male-specific lethal* (*msl*) genes *msh-1*, *msh-2*, and *msh-3*, and *males absent on the first* (*mof*)] and two non-coding RNAs [*roX1* and *roX2*] is essential for dosage compensation in males by binding to the X chromosome in order to suppress X-linked gene expression. In females, dosage compensation (i.e., upregulation of X-lined genes) is prevented by *msh-2* expression repression by the SXL protein (Marín *et al.*, 2000).

As stated above, in the moth *O. scapularis*, the sex of ZZ offspring produced by *Wolbachia*-infected mothers are determined as female, and thus, genes on the Z chromosome are overexpressed by the dosage compensation mechanism, which is considered to be the cause of ZZ-specific deaths (Fukui *et al.*, 2015; Sugimoto *et al.*, 2015).

Fig. 5 Number of sex chromosomes (e.g., X chromosomes) differ between males and females. Dosage compensation occurs in order to equalize sex chromosomal gene dose between the sexes. (a) In *Drosophila*, X-linked gene expression is doubled only in males. (b) In mammals, X-linked gene expression derived from one of the parent is silenced (random X inactivation). (c) In nematodes (*Caenorhabditis elegans*), X-linked gene expression of hermaphrodites (XX) are halved as compared with that of XO males.

GAMETE STRUCTURE

Gamete Structure: Egg, Comparative Vertebrate

Damien B Wilburn and Willie J Swanson, University of Washington, Seattle, WA, United States

© 2018 Elsevier Inc. All rights reserved.

Sexual reproduction in vertebrates requires the fusion of egg and sperm to produce a viable embryo, yet the contributions of each gamete to the developing zygote are extraordinarily different. While sperm provide very little beyond genetic information to the developing organism, eggs (or ova) are highly specialized cells which possess a range of unique features that are essential for both sperm recognition and providing nutrients to the embryo. Between and within vertebrate classes, ova are highly variable in the size and composition of their subcellular compartments which are essential for the initiation (and often completion) of embryonic development. While most vertebrate somatic cells are $\sim 10\text{--}20\text{ }\mu\text{m}$, ova are much larger, often by orders of magnitude and even visible to the naked eye. The smallest eggs are found in the placental field vole (*Microtus agrestis*) at $\sim 50\text{ }\mu\text{m}$ in diameter, while the largest known ova are likely those of the frilled shark (*Chlamydoselachus auguineus*) which are $\sim 15\text{ cm}$ wide and $\sim 1.7\text{ L}$ in volume. Fish often have eggs with diameters on the order of $\sim 1\text{ mm}$, amphibians $\sim 1\text{--}10\text{ mm}$, birds and reptiles $\sim 10^1\text{--}10^2\text{ mm}$, and mammals the smallest with eggs of 10^{-1} mm . These sizes often reflect aspects of the animals' life histories, and more specific examples are included in Table 1 (Lombardi, 1998).

Table 1 Vertebrate egg sizes

Species	Approximate Diameter
<i>Agnatha</i>	
American brook lamprey (<i>Lethenteron appendix</i>)	1 mm
Atlantic hagfish (<i>Myxine glutinosa</i>)	20 mm
<i>Chondrichthyes</i>	
Whale shark (<i>Rhincodon typus</i>)	150 mm
Spadenose shark (<i>Scoliodon laticaudus</i>)	800 μm
<i>Osteichthyes</i>	
Zebrafish (<i>Danio rerio</i>)	800 μm
Threespined stickleback (<i>Gasterosteus aculeatus</i>)	1.5 mm
Western mosquitofish (<i>Gambusia affinis</i>)	1 mm
Shiner perch (<i>Cymatogaster aggregate</i>)	300 μm
<i>Amphibia</i>	
African clawed frog (<i>Xenopus laevis</i>)	1.2 mm
American bullfrog (<i>Rana catesbeiana</i>)	1.5 mm
Mexican axolotl (<i>Ambystoma mexicanum</i>)	2.3 mm
Eastern red-backed salamander (<i>Plethodon cinereus</i>)	3.5 mm
<i>Reptilia</i>	
Corn snake (<i>Pantherophis guttatus</i>)	30 mm
Carolina anole (<i>Anolis carolinensis</i>)	5 mm
Leatherback sea turtle (<i>Dermochelys coriacea</i>)	50 mm
<i>Aves</i>	
Chicken (<i>Gallus gallus</i>)	40 mm
Ostrich (<i>Struthio camelus</i>)	150 mm
Ruby-throated hummingbird (<i>Archilochus colubris</i>)	10 mm
Southern brown kiwi (<i>Apteryx australis</i>)	120 mm
<i>Mammalia</i>	
Human (<i>Homo sapiens</i>)	120 μm
House mouse (<i>Mus musculus</i>)	70 μm
Golden hamster (<i>Mesocricetus auratus</i>)	80 μm
Pig (<i>Sus scrofa domesticus</i>)	100 μm
Short-beaked echidna (<i>Tachyglossus aculeatus</i>)	4 mm
Platypus (<i>Ornithorhynchus anatinus</i>)	3 mm

Beyond the nucleus, the structure of vertebrate oocytes can be divided into three major layers: from inside to outside are the medulla, the cortex, and the accessory envelopes. Each of these regions can be further subdivided, and vary in size and molecular composition between species. Focusing initially on the medulla, it can also be referred to as the egg yolk, containing both the hyaloplasm (cytosol or the formative yolk) and the deutoplasm (nutritive yolk). The primary function of the deutoplasm is to provide additional nutrients for cell division and differentiation of the developing embryo, and contains granules that consist of vitamins, minerals, lipids, and proteins. In placental mammals – where developing offspring receive additional nutrients from the mother – the size of the deutoplasm is quite small (reflected in the decreased cell size of mammalian eggs), yet the opposite pattern is observed in birds and reptiles where gestation occurs entirely within the ovum. The distribution of the fatty, proteinaceous granules of the deutoplasm are also variable: ova with large quantities of yolk are termed *macrolecithal*, while those with little or no yolk are termed *microlecithal* and *alecithal*, respectively. Ova are further described by the distribution of the deutoplasm, such that those with highly polarized granules are termed *telolecithal* and those with central granules are termed *centrolecithal* (Lombardi, 1998). In non-eutherian vertebrates, the principal precursor of the lipoproteins found in deutoplasm is vitellogenin. Synthesized in the liver in response to elevated estrogen, multiple genes code for different isoforms of vitellogenin and vary by taxon: teleost fish have between 3 and 5 gene copies, African clawed frogs have 2 gene copies, and both chickens and platypuses have 3 gene copies (Babin, 2008). After hepatic secretion, vitellogenins circulate in the blood stream and are endocytosed by developing ova where they are proteolytically cleaved and lipidated. These modified vitellogenin products are packaged with phospholipids, neutral lipids, and small amounts of glycogen to produce the deutoplasm granules for nutritifying developing embryos (Kardong, 2006). In some fish, circulating plasma vitellogenin can serve additional functions, such as binding to bacteria and fungi to improve recognition and clearance by the immune system (Li *et al.*, 2008). The small eggs of eutherian (placental) mammals mostly lack a deutoplasm, as nutrition is primarily supplied by the mother during gestation. Coinciding with this transition from ovovivipary (egg-laying) to vivipary (internal gestation), the vitellogenin genes in eutherian mammals have been lost to pseudogenization, and instead the emergence of casein genes facilitates lactation (Brawand *et al.*, 2008).

Surrounding the medulla is the cortex, which contains the plasma membrane (oolemma) and the adjacent cytoplasm (cortical ooplasm). Compared to somatic plasma membranes, the oolemma contains multiple specialized proteins that confer unique features, such as rapid endocytosis, cell junctions with overlaying follicle cells, and recognition of sperm. In most vertebrate clades, binding of sperm causes a change in the ion content of the cortical ooplasm, altering the oolemma polarity and preventing multiple sperm from fusing with the oocyte (polyspermy) (Lombardi, 1998). While polyspermy is extraordinarily toxic to most oocytes, its notable that birds have no blocks to polyspermy, with the oocyte nucleus still fusing with only a single sperm nucleus (Ichikawa *et al.*, 2016). In fish, amphibians, mammals, and some reptiles, the cortical ooplasm contains large vesicles termed cortical granules that fuse with the oolemma upon fertilization, releasing proteins and mucopolysaccharides that likely serve in blocking polyspermy through unknown mechanisms (Guraya, 1989). The limited availability of material from cortical granules (picograms per oocyte) has impeded thorough characterization of its contents across diverse taxa, but several proteins have been identified in different mammalian species. For example, serine proteases and ovoperoxidase are released that result in remodeling of the zona pellucida (discussed in further detail below) that prevents recognition by sperm; calreticulin is a chaperone that also a lectin that may bind and block critical glycans involved in oocyte-recognition by sperm; similarly, N-acetylglucosaminidase may remove essential glycans from glycoproteins recognized by sperm on the oolemma or accessory envelopes (Liu, 2011). While few pairs of interacting egg and sperm proteins have been identified in any organism (Wilburn and Swanson, 2016), biochemical studies of laboratory mice have identified a likely common molecular basis of oolemma recognition in mammals. Folate receptor 4, renamed Juno after the Roman goddess of fertility marriage, is a GPI-anchored extracellular protein on the oolemma that binds to the sperm surface protein Izumo1, tethering the gametes to allow eventual plasma membrane fusion through unknown mechanisms (Fig. 1) (Bianchi *et al.*,

Fig. 1 Molecular basis of mammalian egg-sperm binding. The sperm surface protein Izumo1 (blue) binds the surface of the oolemma through the egg receptor Juno (pink). The interaction of Izumo1-Juno is species-specific, and following fertilization, Juno is shed from the oolemma by exocytosis to prevent polyspermy. The binding of Izumo1 and Juno only tethers mammalian gametes, and a second but currently unknown set of interactions induces fusion of egg and sperm.

2014; Aydin *et al.*, 2016). Izumo1 recognizes Juno in a species-specific manner, and may play a role in preventing hybridization. In mammals, following the change in oolemma polarity, vesicles containing Juno are exocytosed which prevents additional sperm from recognizing the oolemma (Bianchi *et al.*, 2014).

The outermost components of the oocyte are the accessory envelopes: barriers that surround the primary oocyte and can perform an array of functions in different taxa, including protection from pathogens, facilitate oxygen transfer, host beneficial microbes, promote sperm binding, and provide blocks to polyspermy (Shu *et al.*, 2015). Classically, accessory envelopes have been divided into three classes based on their site of origin: primary accessory envelopes are produced by the developing oocyte, secondary accessory envelopes are deposited by surrounding follicle cells, and tertiary accessory envelopes are derived from other parts of the female reproductive tract (Lombardi, 1998). However, as our biochemical understanding of the molecules that constitute accessory envelopes has become more sophisticated, these delineations break down as some envelopes contain molecules from multiple sources (Modig *et al.*, 2006). Between the accessory envelopes and oolemma is the fluid filled perivitelline space, which can widen as both the oocyte and surrounding follicle cells secrete material into it. At least one accessory envelope – the vitelline envelope (VE) – is common to all vertebrate oocytes, yet historically its name has varied between taxa. In fish, it is often referred to as the chorion; in amphibians, reptiles, and birds, it is the vitelline membrane; and in mammals, it is the zona pellucida. The glycoproteins that constitute the VE (described in further detail below) can be synthesized directly by the oocyte, the surrounding follicle cells, or by the liver and transported via the bloodstream, blurring its classification as a primary, secondary, or tertiary accessory envelope. The accessory envelopes that overlay the VE vary dramatically between different vertebrate classes (Fig. 2). In eutherian mammals, a group of follicle cells adhere to the VE and form the corona radiata, providing essential proteins to the developing ovum. In reptiles and birds, since embryogenesis occurs entirely inside the egg before hatching, the VE is surrounded by a thick layer of albumin which acts as a nutrient source during development. This albumin layer is then surrounded by a keratinous shell membrane. In reptiles, the shell may be composed of one or more separate keratin layers, and the outermost layer may also be impregnated with calcium carbonate. In birds, the albumin layer is significantly more heterogeneous and partially separated by chalazae: spirals of fibrous material that act as ligaments, holding the ovum in the center of the more fluid albumin layer. Additionally, the outer shells of bird eggs are always highly calcified. In amphibians, the VE is surrounded by up to eight concentric layers of neutral mucopolysaccharides and mucoproteins that often allow them to adhere to substrates. Given the diversity of habitats and life strategies for amphibians, these tertiary accessory coats often possess unique features: for terrestrially breeding species, the outer layers are highly permeable to water to provide a hydration reservoir for the egg; some species embed toxins to reduce risk of predation; and in some *Ambystoma* spp., the

Fig. 2 Schematic of oocyte structure between vertebrate groups. All vertebrate oocytes share a common base structure of a nucleus with condensed nuclei, surrounded by nutrient rich cytoplasm (medulla) and plasma membrane (oolemma). Except for eutherian mammals, the medulla contains large quantities of vitellogenins that comprise the nutritive yolk. The vitelline envelope (VE) is a glycoprotein coat that encapsulates the oocyte, and goes by multiple names depending on the taxon. In teleost fishes, the VE contains a small hole (micropyle) which is the sole point of entry for sperm. Other groups have additional tertiary envelopes that surround the VE: in amphibians, these are concentric rings of mucoidal compounds that confer several properties; in reptiles, birds, and monotremes, there is a dense albumin layer that is a nutrient reservoir for the developing embryo contained with a keratinous shell membrane (and often a calcified shell); in mammals, follicle cells adhere to the VE and form a cellular tertiary envelope termed the corona radiata. Adapted from Lombardi, J., 1998. *Comparative Vertebrate Reproduction*, vol. 1, first ed., US: Springer.

Fig. 3 Genetics of ZP proteins between vertebrate classes. Six major gene families of ZP proteins are found across vertebrate clades: ZP1, ZP2, ZP3, ZP4, ZPD, and ZPAX. Presence of genes and pseudogenes are denoted by filled and open circles, respectively. In many teleost fish species, ZP3 is highly duplicated and persists as multiple paralogs in each genome. In the branch leading to eutherian mammals, ZPD and ZPAX have both been lost, with ZPAX still being detectable as a pseudogene in many mammalian genomes. Critically, these data only reflect genomic presence and not protein abundance in vertebrate VEs (where there is limited data for most species).

accessory coats can host algae that increase available oxygen and remove nitrogenous wastes for the embryo. In contrast to the aforementioned groups, teleost fish lack additional accessory envelopes (Lombardi, 1998).

The VE is composed of multiple homologous glycoproteins often referred to as ZP proteins based on their original characterization in mammals. There are six major gene families that code for ZP proteins: ZP1, ZP2, ZP3, ZP4, ZPD, and ZPAX. Phylogenetically, ZP3 has been hypothesized to be the oldest ZP protein family (Claw and Swanson, 2012), but across different vertebrate clades, each of the six classes has exhibited varying degrees of gene duplication, pseudogenization, and gene loss (Fig. 3). For example, several fish species contain multiple paralogs of ZP3, yet it exists as a single copy in most tetrapods; similarly, while ZP4 is present in most mammalian species, it has been lost in rodents (Shu *et al.*, 2015). Despite many genomes containing multiple ZP protein coding genes, expression is unequal and the proteins account for different percentages of the VE proteome. In mammals, ZP2 and ZP3 are the major components, each comprising ~45% of the zona pellucida, with ZP1 and ZP4 only constituting ~5% each (in rodents, ZP1 is ~10%) (Moos *et al.*, 1995). In birds, the vitelline layer is principally composed of hepatic ZP1 and follicular ZP3, with minor amounts of ZP2, ZP4, and ZPD, and no ZPAX (Ichikawa *et al.*, 2016). Less is known about the composition of fish, amphibian, and reptilian VEs. A defining feature of ZP proteins is the presence of a ZP module: a structural motif consisting of adjacent ZP-N and ZP-C domains, two independent protein domains with predominantly β -sheet structures that can polymerize into filamentous aggregates and form the basic architecture of VE. While the ZP module was named based on its original identification in the mammalian VE, it is also found in other vertebrate proteins involved in kidney function, innate immunity, and cancer (Bokhove *et al.*, 2016). In biochemical experiments expressing each domain separately, ZP-C exists as a monomer while ZP-N homodimerizes, suggesting that it is the principal component that promotes VE polymerization (Monne *et al.*, 2008). ZP proteins are often elaborated with additional protein features, such as N- and O-linked glycosylation, additional ZP-N domains, or other protein domains (e.g., trefoil) (Fig. 4). Tandem repeats of ZP-N domains seem to be a common feature of ZP proteins, and appear to be gained and lost multiple times throughout evolutionary time, yet their precise functions are unknown (Callebaut *et al.*, 2007). At least in some marine invertebrates, such tandem arrays play a critical role in sperm recognition and possibly restricting polyspermy (Wilburn and Swanson, 2016).

While the specific molecules that mediate egg-sperm interactions are poorly characterized, the VE and other accessory envelopes play differing roles in mediating sperm binding and/or preventing polyspermy within each vertebrate group. For most taxa, the overarching cellular events have been characterized, with the precise molecular details yet to be determined. In teleost fishes where the VE is the only accessory envelope, the sole point of passage for sperm is a small hole in the VE surface termed the micropyle. It is hypothesized that sperm are attracted to the micropyle via chemoattraction, inevitably guiding them to the oolemma where fusion will occur. In amphibians, sperm penetrate the multilayered mucosal accessory envelopes through unknown mechanisms, yet in some species, this penetration is necessary to activate sperm for fusion with oolemma. In birds, sperm specifically bind the VE through glycans attached to the ZP proteins. As hepatically synthesized ZP1 is circulating in the female bloodstream, it is posttranslationally modified with ubiquitin: a common peptide tag which targets proteins for degradation. To penetrate the VE, proteases are secreted from the sperm acrosome that recognize this ubiquitin moiety, resulting in proteolysis that creates a hole through which sperm can pass. Bird oocytes have no blocks to polyspermy, and it is common for multiple sperm nuclei to coexist in the zygote. Through unknown mechanisms, the oocyte nucleus will select and fuse with a single sperm nucleus, the additional nuclei are degraded, and a normal diploid animal is produced. In mammals, to permeate the corona radiata, sperm release hyaluronidase from the acrosome to degrade glycosaminoglycans which bind the associated follicle cells to the VE. Next, sperm recognize the

Fig. 4 Phylogeny and structure of ZP proteins. Across vertebrate evolution has emerged six major families of ZP proteins (ZP1, ZP2, ZP3, ZP4, ZPD, and ZPAX). Each ZP protein contains signal peptide which targets it to the extracellular matrix and a ZP module that consists of adjacent ZP-N and ZP-C structural domains. Beyond this conserved module, the additional ornamentalations in each protein vary, and include additional N-terminal ZP-N repeats and trefoil domains. Except for ZPAX, each ZP protein contains a C-terminal transmembrane domain that anchors it to the oolemma, and following proteolytic cleavage at the furin cleavage site, the ZP proteins are released into the VE. The large N-terminal region of ZPAX has not been characterized, and it is unknown if it contains additional domains. A tree denoting the phylogenetic relationship of the ZP proteins is included; while ZP3 is thought to be the ancestral gene, its exact position in the tree is unknown (denoted using a grey line). Adapted from Wilburn, D.B., Swanson, W.J., 2016. From molecules to mating: Rapid evolution and biochemical studies of reproductive proteins. *Journal of Proteomics* 135, 12–25 (schematics for ZP1, ZP2, ZP3, and ZP4 are based on the human homologs, with ZPD and ZPAX based on the homologs from *Xenopus tropicalis*).

VE in a species-specific manner via the first ZP-N domain of ZP2 (Avella *et al.*, 2014; Wilburn and Swanson, 2017). There is debate whether mammalian sperm penetrate the zona pellucida using proteases (like birds) or through non-enzymatic mechanisms (similar to marine invertebrates, (Lewis *et al.*, 1982)), but regardless of the mechanism, sperm create a hole in the VE that allows passage into the perivitelline space. Finally, fusion occurs after binding of Izumo1 and Juno at the gamete plasma membranes, completing fertilization. In addition to exocytosis of Juno, secretion of specific proteases and zinc ions from the oocyte causes hardening of the VE, preventing further sperm penetration and reducing polyspermy risk (Que *et al.*, 2017).

In summary, oocytes are a fascinatingly complex type of cell that vary dramatically between vertebrate clades: as part each organism's life history, a number of unique molecular and cytological phenotypes have emerged. The diameter of vertebrate oocytes spans four orders of magnitude, and common cellular features such as the VE are still extraordinarily variable at the genomic scale. The hepatic origin of both vitellogenins and some ZP proteins demonstrate complex inter-tissue dynamics, and the repeated expansion and loss of these genes over evolutionary time correspond to changes in life strategy. Perhaps the most essential and novel feature of ova is species-specific recognition and fusion with sperm: while birds uniquely have no blocks to polyspermy, distinct sets of accessory envelopes and surface proteins on the oolemma provide molecular barriers that permit precise regulation over fertilization rates. Despite more than 100 years of studying fertilization in diverse taxa, the molecular underpinnings of egg-sperm interactions remain to be elucidated, and represents a key research challenge in the future.

Sperm: Comparative Vertebrate

Peter D Temple-Smith, Aravind Ravichandran, and Fabrizio E Horta Nunez, Monash University, Clayton, Australia

Introduction

The subphylum Vertebrata contains all the animals that develop a cartilaginous or bony vertebral column and a well-developed cranium (head) during embryogenesis. The group contains six groups: sharks and rays (Chondrichthyes), fishes (Osteichthyes), frogs and their relatives (Amphibia), birds (Aves) and the three orders of mammals – Prototheria/Monotremata (platypus and echidnas), Marsupials/Metatheria (the marsupials) and the Placentals (*Note: while the term placental mammals is used throughout the literature as a common name for the Eutheria, it is clear particularly since the 1970s that all marsupials also develop a functional placenta during their short period of gestation and are placental mammals.*)/Eutheria. The eutherians are the largest group of mammals containing all the species from mice to men.

The vertebrates display a broad range of reproductive characteristics that include external and internal fertilization, specialised egg (oocyte) structures, a wide variety of social structures and mating behaviours, pair bonding, mate guarding and sperm competition. These characteristics as they appear in various species and groups have influenced the evolution of sperm structure and function to ensure successful reproduction.

General Sperm Structure in Vertebrates

Throughout the animal kingdom, including the vertebrates, sperm structure is highly conserved and consists of a head containing the hereditary information in the form of DNA, arranged as chromosomes and neatly packaged into the nucleus, which is the main component of the head. In vertebrates, a neck or connecting piece usually attaches the head to the sperm tail or flagellum (**Fig. 1**). The sperm tail is usually subdivided into a midpiece and a principal piece and has the capacity to produce chemical energy in the form of adenosine triphosphate (ATP), from the power generators of the cell – the mitochondria. The mitochondria, which vary greatly in size, shape and number between species are usually associated with the proximal part of the tail, adjacent to the neck, to form the midpiece. The principal piece, which is usually the longest part of the spermatozoon, uses the energy from the ATP to provide the motive force through a structure called the axoneme or axial filament. The axoneme usually extends from the neck to the end of the tail and in most spermatozoa has a distinctive 9+2 microtubule structure which is also common to other

Fig. 1 Showing variations in sperm structure across different vertebrates. (a,b): Toad Fish, Elasmobranch (Fish); (c-e) Toad, Frog, Salamander (Amphibians) (f) Lizard; (g,h) Frigilla, Domestic fowl (Birds); (i) Monotreme (Echidna); (j,k): Mouse, Man (Eutheria) (Chordate Zoology by P.S.Verma).

motile organelles in the body, for example cilia. The critical function of the axoneme in all motile organelles and cells such as spermatozoa is to cleave a high energy phosphate molecule from the ATP and convert the chemical energy released from the ATP into mechanical energy that moves the tail and creates the forward motility that is required to reach and fertilise the oocyte.

Sperm Structure in Relation to Functions of Vertebrate Spermatozoa

In the previous section sperm structure in vertebrates has been described as highly conserved but there is also a close relationship between the evolution of structural and functional specialisations of vertebrate spermatozoa and the need to ensure successful fertilization of the oocyte (Bedford, 2004). Irrespective of whether spermatozoa are released externally in a cloud over a mass of released oocytes or ejaculated directly into the female and then required to swim through the female reproductive tract by movements of their tails to meet and fertilise the ovulated egg, sperm motility is needed to ensure that the spermatozoon makes contact with the oocyte during fertilization. In general, with external fertilization the main role of the tail is to move the spermatozoon to the surface of the oocyte. In species that practise internal fertilization the tail is required to move the spermatozoa from the site of deposition, usually in a cloaca, urogenital sinus or vagina but in some species directly into the uterus or part of the oviduct which receives the oocyte(s) at ovulation. This distance can vary from a few millimetres or centimetres in small species like small sharks, fish, reptiles, birds and mammals to a metre or more in some large species like elephants and whales. For these relatively long distances, forward progressive sperm motility is an absolute requirement, although smooth muscle contractions have also been shown to assist in sperm transport through the female tract. The most critical element in the process of fertilization is the successful penetration of the spermatozoa through the vestments around the oocyte, such as layers of follicle cells and a jelly coat or zona pellucida, to reach the surface of the oocyte and then fuse with the plasma membrane that encloses the oocyte. Fusion of sperm and egg membranes is a prerequisite for fertilization and for entry of the sperm nucleus into the cytoplasm of the oocyte. Usually for the spermatozoon, enzymes released from the acrosome, in addition to sperm motility, are required to assist the fertilizing spermatozoon to reach the oocyte and incorporate its nucleus into the oocyte cytoplasm. The acrosome covers the tip of the sperm head, and in some vertebrates, especially in the Class Mammalia, it may cover up to 2/3 rds of the anterior region of the head. The acrosome is a sac of enzymes that mostly breakdown proteins. When spermatozoa approach the oocyte the acrosome undergoes an acrosome reaction to release its contents which assists the spermatozoon, aided by the motility created by energy produced by the mitochondria and the motive force of the axial filament in the tail, to reach and enter the oocyte at fertilization.

Comparative Features of Vertebrate Spermatozoa in Relation to Their Phylogeny

Chondrichthyes

Chondrichthyes is a class that contains sharks, skates, rays and chimeras. They are jawed vertebrates, with skeletons made of cartilage instead of bone. The class can be divided into two subclasses; Elasmobranchii (sharks, rays, skates, and sawfish) and Holocephali (chimaeras). In terms of the spermatozoa present in this class, chondrichthyes appear as a simple and a homogeneous group. The chondrichthyan spermatozoa structure is generally similar to other vertebrates and consists of a head containing the nucleus and acrosome, a midpiece containing mitochondria and a tail showing an axoneme with microtubular arrangement in a typical 9+2 or 9+0 pattern (Fig. 2(a)).

The sperm head in Chondrichthyes is long (>30 µm) and helical in shape (Fig. 1(b)), with a moderately elongated conical acrosome present apically. The spermatozoa of some Chondrichthyes with helical head shape present different intranuclear fibres that join together during spermatogenesis. It has been suggested that these structures finally form the fibrillar nuclear sheets (Jamieson, 2001). The long midpiece of elasmobranch sperm consists of an axial rod around which the mitochondria are arranged (Fig. 1(b); Mattei, 1988). The axial rod is a structure present in some amphibians and unique to the class Chondrichthyes within fish. The axial rod forms nine coarse fibres at the centre of the sperm midpiece (Jamieson, 1991). The flagellum (or tail) is comprised of two key structures, the central axoneme and the longitudinal columns. In order to produce the sperm motility, the central axoneme rotates along the length of the flagellum. In contrast, the longitudinal columns remain fixed at doublet positions 3 and 8 (Fig. 2(b)). These characteristics allow the creation of a double helix structure (Jamieson, 1991).

Possible differences between the Elasmobranchii and Holocephali has been difficult to characterize. However, the Holocephali show a reduced longitudinal column at the position 8, a longer midpiece and absence of the proximal centriole compared to elasmobranchs (Fig. 2(c)). In spite of these findings, further studies are warranted to describe these possible differences with certainty. Interestingly, there are no spermatozoa features that separate sharks from rays. Nevertheless, it has been established that in terms of sperm metrics there is a species-specific variation among all Chondrichthyes (Jamieson, 1991).

Osteichthyes

Osteichthyes, commonly referred to as the bony fish, is the largest class of vertebrates in the animal kingdom. They are a very diverse group which includes 45 orders with more than 28,000 species currently identified (Betancur-R *et al.*, 2013). The group Osteichthyes is characterised by fish species that have skeletons primarily composed of bone and is divided into the ray-finned fish (Actinopterygii) and lobe-finned fish (Sarcopterygii).

Fig. 2 Chondrichthyes, Osteichthyes and Amphibian spermatozoa. (a) Example of Chondrichthyes spermatozoa indicating head of helical shape, midpiece and tail. (b) Elasmobranchii spermatozoa flagellum in transversal sections, showing longitudinal columns in position 3 and 8. (c) Holocephali flagellum possibilities in transversal sections, showing a reduced longitudinal column at position 8 or absence of it. (d) Example of Osteichthyes spermatozoa. Reproduced from (a) Jamieson, B.G., 1991. *Fish Evolution and Systematics: Evidence from Spermatozoa: With a Survey of Lophophore, Echinoderm and Protochordate Sperm and an Account of Gamete Cryopreservation*, Cambridge: Cambridge University Press. xiv + 319pp. doi:10.1046/j.1420-9101.1992.5040721.x. (b) Jameison, B.G., 2005. In: Hamlett, W. (Ed.), *Reproductive Biology and Phylogeny of Chondrichthyes*. Science Publishers, pp. 201–236 (Chapter 7).

The structure of the spermatozoa, as in most vertebrates, consists of a head, midpiece and tail (**Fig. 2(d)**). The spermatid nucleus is elongated. The midpiece is very short; and contains two centrioles, mitochondria, and a dense body. However, specific features include the flagellar apparatus that contains an axoneme, with a 9+0 or 9+2 microtubular pattern and a flagellar membrane that presents two lateral extensions situated in line with the central tubules of the axoneme. These form two sidefins which are particularly developed in *Neoceratodus* and other fishes such as Actinopterygians. The periaxonemal cytoplasm is of average density and the tips of the sidefins in *Neoceratodus* contain an opaque substance (Mattei, 1988). The adaptive significance of the lateral fins and undulating membranes is unclear but presumed to enhance swimming capacity (Pitnick *et al.*, 2009). Recent studies exploring the significance of fins in spermatozoa have shown that the swimming capacities of these spermatozoa are enhanced by hydrodynamic characteristics (Gillies *et al.*, 2013).

Other examples include Chondrosteans, that possess similar characteristics but their membrane forms two short sidefins, and the Teleosts, that show a broad diversity of structure in their spermatozoa. Although approximately 95% of these fishes are external fertilizers, specific adaptations in sperm size are seen in those practising internal fertilization. Teleosts spermatozoa, which fertilise internally, are characterised by an elongated midpiece. Teleosts also differ from other vertebrates by lacking an acrosome. This adaptation reflects a mode of fertilization in which spermatozoa do not penetrate the zona pellucida, because they enter the egg through the micropyle, which is a small opening in the egg. A teleost example is the African butterfly fish (*Pantodon buchholzi*) which has an unusually long midpiece and reproduces by internal fertilization. Furthermore, sperm size is widely held to evolve as a consequence of postcopulatory sexual selection (Pitnick *et al.*, 2009). As most of fishes are external fertilizers, high levels of sperm competition can be present particularly in some promiscuous species to achieve fertilization and successful reproduction.

Amphibia

Amphibians are a special class of vertebrates that have demonstrated a variety of evolutionary tendencies in their reproductive biology compared to their aquatic counterparts, the fishes. The class includes three orders: Anura (comprising frogs and toads); Urodela (Salamanders) and Gymnophiona (Caecilians). The anurans predominantly practise external fertilization with a few exceptions like tailed frog (*Ascaphus truei*); the urodeles and caecilians embrace internal fertilization. This difference between the orders has specific implications in the evolution of their spermatozoa, with acquisition of unique morphological characteristics to optimise the reproductive process.

Unlike the primitive aquatic species which possess a basic sperm structure like a rounded head, small midpiece and simple, thin flagellum, the spermatozoa of amphibians, in general, are more filiform, showing an elongated head, tapering acrosome and

a perforatorium. The midpiece and tail are well developed and show specific morphological adaptations such as a rigid 'axial rod' that forms the main axis of the tail displacing the axoneme laterally and an undulating plasma membrane called 'lamellipodium' that traverses the length of the axoneme generating propulsive forces that bring about sperm motility.

The three orders differ in certain sperm characteristics that may be explained by the type of fertilization practised. In anurans that reproduce by external fertilization, where sperm motility is less significant, the spermatozoon is generally short (~40 µm). In primitive anurans, belonging to families Ascaphidae and Discoglossidae, the head possesses a conical acrosome, nucleus with poorly compacted chromatin, an ill-defined perforatorium and endonuclear canal (Fig. 3(a)). The axial rod is short and surrounded by mitochondria. The insertion of the tail is postnuclear in most of the primitive members except *Bombina orientalis* where it is prenuclear (Lee and Kwon, 1996) (Fig. 3(b)). In contrast, higher anurans in the Suborder Neobatrachia, show a structural evolution characterised by the disappearance of the perforatorium, endonuclear canal and axial rod. The urodeles are much closer to primitive anurans than the advanced group, but with certain atypical features. The spermatozoon is longer, measuring ~290 µm and the head consists of a clover-shaped acrosome, a prominent acrosomal barb and sub-acrosomal rod, a nuclear ridge, highly compacted chromatin, a discrete endonuclear canal and perforatorium (Fig. 3(c); Lee and Kwon, 1996). The axial rod is longer and stiffer with abundant mitochondria encircling the axial rod in most families, except Hynobiidae and Cryptobranchidae where it is perinuclear (Fig. 3(c)). These structures suggest a phylogenetic adaptation to support sperm kinetics that assists internal fertilization in urodeles. The caecilians resemble urodeles in structure, with spermatozoa measuring 75–105 µm in length. The acrosomal vesicle shows three distinct zones and a base plate. The flagellum consists of a 9+2 axoneme and an axial rod enclosed by a plasma membrane. Anteriorly, both structures lie close together in the midpiece but when traced posteriorly along the tail, they diverge and the leaves of the undulating membrane become separated by an increasing layer of abundant cytoplasm (Scheltinga *et al.*, 2003).

Reptilia

Reptiles are a spectacular class of ectothermic vertebrates that show impressive variations in physical and behavioural traits among its different members. Their particular physiological and morphological adaptations are important in understanding the evolution of reproduction in mammals. Class Reptilia includes four conspicuous orders namely, Chelonia (turtles and tortoises), Rhynchocephalia (tuatara), Squamata (lizards and snakes) and Crocodylia (crocodiles and alligators). In reptiles, internal fertilization is universal. Reptilian reproduction is characterised by multiple male mating (polyandry) that facilitates sperm selection and also decoupled insemination and fertilization mandating long term sperm storage.

Fig. 3 Variations in sperm ultrastructure of Anurans (a & b) and Urodeles (c). (a) *Discoglossus pictus* (Anura) showing filiform head, inconspicuous neck and a principal piece showing post-nuclear axonemal insertion. (b) *Bombina orientalis* (Anura) with pre-nuclear insertion of axoneme and periaxonemal mitochondria. (c) *Hynobius leechii* (Urodele) showing a clover-shaped head, axial rod (AR) and perinuclear mitochondria (M). Adapted from Lee, Y.H., Kwon, A.S., 1996. Ultrastructure of spermatozoa in Urodela and Primitive Anura (Amphibia) with Phylogenetic considerations. *Anim. Syst. Evol. Divers.* 12(3), 253–264.

The reptilian spermatozoon is filiform and curved. It possesses a head, neck, midpiece with abundant mitochondria and a principal piece containing a 9+2 axoneme surrounded by heavily electron-dense fibrous sheaths resembling higher order mammals and variable in length among the four orders. The undulating membrane seen in amphibians is conspicuously absent, probably implying limited success of nature's experiment with amphibian spermatozoa. The chelonian spermatozoon is 50–55 μm long. The head consists of a perforatorial cap, cephalad to a compact nucleus containing deeply penetrating intranuclear tubes (Fig. 4). The distal centriole is peculiar with central microtubules running its entire length caudally and surrounded by 9 peripheral triplets. Laminated mitochondria are characteristic and are considered an adaptation to support sperm viability during protracted storage (Hess *et al.*, 1991). Storage even as long as three years has been noted. Sperm motility is also highest at low temperatures, perhaps pointing towards influence of copulatory milieu.

Sperm head from a tuatara shows a pointed acrosome, helical nucleus with tip constriction and paired endonuclear canals (Healy and Jamieson, 1994). A dense body lateral to the centriole is notable and shared by snakes and crocodiles. Most of the epididymal spermatozoa show huge cytoplasmic droplets suggesting a protracted maturation phase. Lizards and snakes produce spermatozoa that have a prominent neck cylinder separating the nucleus from midpiece. In lizards, the head shows a singular, para-crystalline perforatorium arising from the apex of the sub-acrosomal cone and an electrolucent zone around the nucleus (Scheltinga *et al.*, 2001). In snakes, mitochondria are abundant (around 14) and are concentrically arranged with an irregular distribution of unique intermitochondrial dense plaques (Hamilton and Fawcett, 1968). Long-term sperm storage is well-established in snakes, especially when egg production and mating seasons are separated. Crocodilians are similar to chelonians in basic morphology but certain features like an inconspicuous neck and presence of both linear and concentric mitochondrial cristae differentiate them from squamates. This mitochondrial specialisation possibly indicates progressive loss of concentric design with evolution.

Fig. 4 Ultrastructure of spermatozoon in Turtle (*Chrysemys picta*), showing the various structural components. Reproduced from Hess, R.A., Thurston, R.J., Gist, D.H., 1991. Ultrastructure of the turtle spermatozoon. *Anat. Rec.* 229 (4), 473–481.

Aves

Birds (Aves) are homeothermic vertebrates that share features inherent to reptiles and mammals. Aves are divided into two Superorders (Palaeognathae and Neognathae) based on the palatal bone framework. Palaeognathae includes the 'flightless' birds (ratites) grouped under four orders: Apterygiformes (Kiwis), Casuariiformes (Emu, Cassowary), Rheiformes (Rheas) and Struthioniformes (Ostriches) and the 'flying' tinamous included under Order Tinamiformes. Superorder Neognathae includes 24 different orders representing all other birds like penguins, fowl, crows, parrots, pigeons and passerines. Reproductive biology in birds is unconventional in various aspects. Testes in birds are intra-abdominal and spermatogenesis occurs even at high temperatures compared with other vertebrates. Extragenital storage is less prominent and spermatozoa are usually released from the testes at ejaculation. Most avian males lack a phallus, with transfer of spermatozoa at insemination by the 'cloacal kiss'. Once ejaculated, the spermatozoa are stored in sperm-storage tubules (SST) of the female for up to two weeks prior to fertilization. In birds, unlike mammals, physiological polyspermy is common and does not impact egg survival.

Sperm morphology shows diversity among the various avian members (Fig. 5). Ratites share certain features with reptiles including a cylindrical sperm head with a pointed acrosome, perforatorium, an elongated nucleus with deep endonuclear canal, a prominent midpiece with abundant mitochondria encircling a long distal centriole and nine dense fibres in the principal piece. Unlike reptiles, the sub-acrosomal cone is absent in birds and the mitochondria have linear cristae instead of a concentric pattern (Jamieson, 2007). The phylogenetic significance of such features remains elusive. A glycogen sheath surrounding the principal piece is seen exclusively in tinamou. Most of the differences in sperm morphology have been postulated by classifying birds into non-passerines and passerines based on the anatomy of the toes that support perching. Non-passerine birds include ratites and certain members of Neognathae while all birds belonging to Order Passeriformes under Neognathae are labelled passerines (song birds). Non-passerine spermatozoa are filiform and closely resemble reptiles (Fig. 5(a)). They possess a perforatorium, two centrioles (proximal and distal), a short midpiece with prominent annulus and a flagellum producing a lashing movement. Passerines, in contrast, have a spirally twisted head resembling a 'corkscrew' with a shorter nucleus (Fig. 5(b)). They lack the perforatorium,

Fig. 5 Non-passerine (a) and Passerine (b) Spermatozoa. (a) Non-passerines: Filiform head resembling reptiles - Rooster (*Gallus gallus*); Tufted duck (*Aythya fuligula*); Domestic duck (*Anas platyrhynchos*); Common guillemot (*Uria aalge*); Corncrake (*Crex crex*); Lesser black-backed gull (*Larus fuscus*). (b) Passerines: Helical (Corkscrew-shaped) head - Song thrush (*Turdus philomelos*); Chaffinch (*Fringilla coelebs*); House sparrow (*Passer domesticus*); Greenfinch (*Carduelis chloris*); Siskin (*Carduelis spinus*). Reproduced from Jamieson, B.G.M., 2007. Reproductive Biology and Phylogeny of Birds, Science Publishers.

proximal centriole and annulus. The mitochondria are interestingly fused into a single helical structure surrounding the axoneme and referred to as the mitochondrial helix. This helicity is likely to contribute to the typical 'spin' witnessed as a part of the forward movement in passerine spermatozoa. The outer, dense fibrous sheath in the principal piece is a more prominent and uniform structure than that described in non-passerines and mammals respectively.

Mammalia

Each of the three infraclasses of mammals (Prototheria, Metatheria and Eutheria) in Class Mammalia have evolved sperm structures that are characteristic of, and specific to each group (Fig. 6). Within the marsupials and eutherians there are genera and families that have evolved new and special structural features that distinguish these groups.

Prototheria

The living order Monotremata in the infraclass Prototheria – platypus (*Ornithorhynchus anatinus*) and up to four species of echidnas (*Tachyglossus aculeatus* and *Zaglossus* spp.) – were derived from therapsid reptiles and are the earliest branching of the mammalian lineage. Monotremes diverged from the other two groups of mammals about 166 million years ago (Mya; Warren *et al.*, 2008) and display their reptilian/sauropsid ancestry in various characters including oviparity and sperm structure. Platypus and echidna spermatozoa are very similar to typical reptilia and avian spermatozoa (Fig. 6(a); Carrick and Hughes, 1982). They are characterised by an elongated, helical and filiform sperm head, consisting of 3–5 turns, about 40 µm in length in the platypus and 50 µm in echidnas and with a small rostrally-positioned acrosome, 5–7 µm in length, which occupies less than a sixth of the length of the sperm head. A characteristic reptile-like feature of monotreme spermatozoa is the circumferential and spiral pattern of condensation of the nuclear contents of spermatozoa that develops in the testis. The sperm tail inserts into the caudal end of the sperm head via a small neck and is divided by a thin fibrous annulus into a midpiece about 5 µm in length, containing the mitochondria, and a principal piece approximately 60 µm long (Fig. 6(a)). A standard 9+2 axoneme extends along the length

Fig. 6 (a) Monotreme spermatozoon (platypus) showing spiral nucleus, junction between the head and tail (arrow) and narrow flagellum. (b) Monotreme sperm bundles in the epididymis (c) & (d). Comparison of the structural specialisations of a generalised marsupial (c) and eutherian sperm head (d). Reproduced from (a) Carrick, F.N., Hughes, R.L., 1982. Aspects of the structure and development of monotreme spermatozoa and their relevance to the evolution of mammalian sperm morphology. *Cell Tissue Res.* 222, 127–141. (b) Gruzner, F., Nixon, B., Jones, R.C., 2008. Reproductive biology in egg-laying mammals. *Sex Dev.* 2, 115–127. (c & d) Temple-Smith, P.D., Comparative structure and function of marsupial spermatozoa. *Reprod. Fertil. Dev.* 6, 421–435.

of the flagellum and 9 very small hemispherical dense fibres are arranged around the axoneme for most of its length; one dense fibre is associated with each outer pair of microtubules in the axoneme. The principal piece features a cortical fibrous sheath in reptilian-like spirals beneath the sperm plasma membrane and lacking the elongated lateral columns that are found in the fibrous sheath in the principal piece of most marsupial and eutherian mammals. These structures are reputed to be present to stiffen the flagellum to improve the wave-pattern of flagellar movements and sperm motility. In all monotremes, the spermatozoa are released singly from the testis but during passage through the epididymis, aggregate into large bundles of often up to 100 spermatozoa. This, with the gradual caudal movement and loss of the residual cytoplasmic droplet, the acquisition of forward progressive motility and development of the fertilizing capacity, provides evidence of the complex role of the mammalian epididymis in post-testicular maturation of spermatozoa. Monotreme spermatozoa are released as sperm bundles at ejaculation (Fig. 6(b)) and are thought to only separate again into individual spermatozoa when they reach the site of fertilization in the oviduct (Gruzner *et al.*, 2008).

Metatheria

The marsupial branch of mammals in the Metatheria, have been separated from the eutherians for about 148 Mya. There are more than 250 living species distributed throughout the Americas and Australasia and characterised by birth, after a short period of gestation, of very early stage neonates that have long periods of development attached to a teat in a pouch or in the mammary area of some pouchless female marsupials. Marsupial spermatozoa vary in length depending on the family with the Australian honey possum and the Dasyuridae (small carnivorous marsupials) producing the largest spermatozoa in excess of 250 μm in length. Spermatozoa from the diminutive honey possum (*Tarsipes spenceri*) are recognised as the longest of any mammal, at about 360 μm . Spermatozoa of marsupials are unique in many aspects of their structure compared to monotremes and eutherians (Temple-Smith, 1994). In all species, with the exception of the American shrew opossums (Caenolestidae) and koala and the three closely related wombat species (Phascolarctidae), the flagellum connects via a long, straight or curved (Didelphidae) articulated connecting piece to a central indentation or implantation fossa in the sperm head (Figs. 6(c) and 7(a)). This articulation enables the sperm head to rotate on the flagellum which occurs as part of the process of sperm maturation during passage through the epididymis and in reverse during capacitation in the female reproductive tract prior to fertilization. Each marsupial family has a characteristic sperm

Fig. 7 (a) Comparison of the structural features of the head and midpiece of mature Australian and American marsupial spermatozoa. [Note that, except for the microbiotherid *Dromiciops glironia*, sperm pairing is restricted to the American marsupials and that each family has a distinct and specific nuclear shape. head shape (Fig. 7(a)) which is generally wedge-shaped and symmetrical with ventral gutter in all Australian marsupials, except the Phascolarctidae, and asymmetrical in all American marsupials with the exception of the microbiotherid *Dromiciops gliroides* – the Chilean monito del monte – which is more similar to sperm structure in many of the Australian marsupial families (Fig. 7(a)). Sperm head length varies from about 2 μm in the cylindrical, bullet shaped caenolestid spermatozoa to 14 μm in the honey possum and the acrosome varies in size and shape from a small button-shaped structure on the anterior aspect of the dorsal surface of the sperm head to a thin layer covering the entire dorsal surface. The koala and wombats show their close evolutionary relationship in having an unusual hook-shaped spermatozoa and a bent connecting piece with a distal insertion to the sperm head (Fig. 7(a) and (i)). They also have the most pleomorphic nuclear structure and shape of any known mammal except perhaps for human spermatozoa; the reason for this variability in sperm head shape is still not clear. The tail extends from the distal end of the connecting piece and is subdivided into midpiece, with 8 to in excess of 15 spirals (gyre) of densely packaged mitochondria depending on species, and principal piece by a very distinct annulus. In most species that have been examined except the Phascolarctidae there is a network of helical sub-membrane fibres that usually encircle the midpiece and extend to the annulus; their function is unknown but they may provide a stabilizing structure for the midpiece. As in some other vertebrate groups, there is a central axial filament consisting of 9+2 arrangement of microtubules and a set of nine outer dense fibres arranged in association with the 9 outer doublet microtubule pairs. The principal piece is the longest part of the tail and is characterised by a fibrous sheath that encloses the axial filament and its outer dense fibres. Unlike non-therian spermatozoa, marsupial and eutherian spermatozoa incorporate two of the dense fibres into the fibrous sheath to form two structural columns for most of the length of the principal piece. The fibrous sheath consists of a series of ribs that connect to the longitudinal columns and are thought to stabilize the sperm tail and direct the forward swimming movements of the spermatozoa. In cross-section the tail is essentially circular and symmetrical in most marsupial species but in those families with longer sperm tails, the cross-sectional shape is ovoid or flattened, a structural adaptation that may assist the unusual serpentine motility observed with extreme sperm tail lengths. One of the most intriguing aspects of marsupial spermatozoa is the structural and functional changes during passage through the epididymis conferring maturational changes in the spermatozoa which are characteristic of only mammalian vertebrates. These include extreme hardening of the dense fibres and fibrous sheath to improve motility, acquisition of the capacity for motility and fertilizing ability, rotational changes in the sperm head on the tail from a T-shape to a streamlined alignment with the tail (Temple-Smith and Bedford, 1976) and the intriguing precise head-to-head formation of sperm pairs in all the American, but none of the Australian, species except *Dromiciops gliroides* that resembles the Australian marsupial fauna and is thought to be phylogenetically the closest American species to Australian marsupials ((Fig. 7(a); Temple-Smith, 1994). The rotational changes of the head and sperm pair formation (Figure b, c and d) in the American marsupials are critical for effective progressive motility in the female tract. Studies show that the American marsupial sperm pairs separate in the oviduct prior to contact with the oocyte.

Eutheria

Of the three major living mammal groups the eutherians are the most abundant in species and diversity with more than 4000 species worldwide from tiny ~40 mm bumblebee bats weighing about 2 g to the more than 40 tons, 30 m long blue whale. Of the living families, the Rodentia is the most diverse consisting of more than 1500 species, and the least diverse is the Tubulidentata containing a single species, the aardvark; the primates contains the highest order of mammals including *Homo sapiens*, the most numerous species on earth. Species in the infraclass Eutheria have a broad range of sperm structures that reflect the functional needs of reproduction, especially sperm motility and fertilizing ability. As with each of the other two groups of mammals the general structure of eutherian spermatozoa is highly conserved but large variations in size, shape and structural specialisations have been reported which often demonstrate close evolutionary links between species, genera and families. The hooked sperm head in many murid rodent spermatozoa is an excellent example of an evolutionary relationship in sperm structure (Figs. 1(j) and 7(e)).

The eutherian spermatozoon structure follows the basic pattern described in the monotremes and marsupials, and also in most of the other vertebrate groups. It consists of the traditional sperm head with nucleus and acrosome, a connecting piece, and a tail divided into midpiece, principal piece and end piece. However some general structural differences set the eutherian spermatozoa apart from the spermatozoa of all other vertebrates including the other two extant mammalian infraclasses. In most eutherians the acrosome covers approximately the anterior 2/3 rds of the sperm head as a cap-like structure. It has obvious specialisations including a distinct equatorial segment, which forms a stable cuff around the middle of the spermatozoa during and after the acrosome reaction, and a postacrosomal region which fuses with the oocyte at fertilization (Fig. 6(d)). Acrosomal enzymes have often been suggested as critical for penetration of the zona pellucida surrounding the oocyte. However, the resilience of the eutherian zona to enzymatic digest suggests that this may not be as critical as originally proposed. More recently it has been suggested that the generally flattened shape of eutherian spermatozoa, the scythe-like perforatorium along the rostrum of the sperm head adjacent to the nucleus (Fig. 6(d)), and the hyperactive motility of the capacitated fertilizing spermatozoon all function to cut a slit-like path through the eutherian zona pellucida for the spermatozoon to gain access to the oocyte (Bedford, 2004). In eutherians, a complex maturation of spermatozoa occurs as they transit the epididymis. This includes the hardening of the sperm head, the outer shell of the mitochondria and the dense fibres and fibrous sheath in the sperm tail by disulphide crosslinking of the proteins in these structures. These specialisations are considered to have evolved to assist with sperm penetration through the eutherian zona pellucida, which is much thicker (6–16 μm , depending on species) than in any other vertebrate group including the marsupials (2–4 μm). This process allows the fertilizing spermatozoon to enter the perivitelline space inside the zona and make contact with the surface of the oocyte. The stable equatorial region of the sperm head is responsible for binding the spermatozoon to the membrane of the oocyte and activating the oocyte as a prelude to successful fertilization in eutherian mammals. The sperm membrane over the

postacrosomal region fuses with the oocyte membrane and release the contents of the nucleus into the cytoplasm of the oocyte to complete the process of fertilization. The dimensions and position of the acrosome is species-specific with some shrews having extremely large acrosomes compared to other eutherians (Bedford, 2004).

Spermatozoa in eutherians in general, display an inverse allometric relationship of sperm length to body size with the longest spermatozoa in rodents and the shortest in some sheep species, the collared peccary and hippopotamus; the Chinese hamster spermatozoa are currently regarded as the longest in the Eutheria with a total length of ~250 µm and midpiece and principal piece lengths of ~100 µm and ~140 µm respectively (Cummins and Woodall, 1985). In general those species with long spermatozoa tend to produce fewer spermatozoa whereas those with small spermatozoa produce large numbers of spermatozoa in their ejaculates. As in the monotremes and marsupials there are some examples of aggregations of spermatozoa in eutherians. In the guinea pig, the spermatozoa group together to form a rouleaux (Fig. 7(e)) during passage through the epididymis and in rodents it is common for them to associate into large aggregates by the hook-shaped head linking to the tail of adjacent spermatozoa after ejaculation (Fig. 7(f)). Like the sperm bundles in the monotremes, the aggregation of rodent spermatozoa appears to improve motility for more efficient passage through the female tract.

Commentary on Evolutionary Specialisations in Vertebrate Spermatozoa

Among vertebrates, polyandry has been observed as an interesting strategy to optimise reproductive success. By subjecting themselves to copulation attempts by multiple males, females have expanded the scope for selection of ideal male gametes for their offspring and at the same time established a competition among spermatozoa from different males to fertilise the ova (Birkhead and Møller, 1998). This has driven the evolution of structural and functional specialisations relating to sperm size, swimming speed, sperm production and energetics among the different classes of vertebrates (Parker and Pizzari, 2010). Evidence from many comparative studies have mostly supported the concept that longer spermatozoa swim faster. Three basic principles explaining this perception include: larger midpieces with abundant mitochondria powering flagellar kinetics; longer tails generating distinct modes of propulsion and an increased tail: head ratio offsetting the head drag that affects sperm velocity. Several morphological observations reported among the different vertebrates provides impetus to such principles. These observations include: helical head in elasmobranchs and holocephali; presence of side fins in sperm tails allowing enhanced kinetics in bony fish; an undulating membrane in amphibians; a larger mid-piece, well-developed long fibrous sheath and linear mitochondrial cristae in reptiles; helical head and mitochondrial helix in birds and various sperm bioenergetic pathways, sperm aggregation, a more complex maturation in the epididymis, and tail modifications that affect the motility in mammals, as seen in some marsupials. Nonetheless, the evidence that sperm competition is the main driving force is far from convincing because other factors like mode of fertilization, chemical characteristics of the seminal fluid, milieu of the female reproductive tract and sperm storage requirements also have potential implications on spermatozoal adaptations.

Conclusions

In this article we have tried to convey both the conservative structure of vertebrate spermatozoa and the amazing diversity of structural specialisation and functional requirements that exists within and between the various orders, infraclasses and classes to ensure successful transport of the sperm nucleus to its final rendezvous with the oocyte at fertilization. The improvements in light microscopy in the early to mid-1900s, followed by the evolution of scanning and transmission electron microscopy in the mid- to late 1900s have provided a detailed analysis of sperm structure and interpretation of the selective processes that have refined their structures, on which this article has been based. More recently the newer sciences of genomics, proteomics and metabolomics, for example, are expanding our knowledge of sperm structure and function and will shape our understanding in the future. This emphasises the need for further comparative research in identifying mechanisms that underlie the structural and functional trade-off reported in vertebrate spermatozoa.

Egg, Comparative Invertebrate

Amy L Moran and Kanoe Morishige, University of Hawai'i at Mānoa, Honolulu, HI, United States

Introduction

With the exception of purely asexual animals, all metazoans pass through a single-celled stage called an 'egg' that is fertilized at the initiation of embryonic development. The diversity of egg structures among invertebrate metazoans is enormous – not surprisingly, since invertebrates comprise all non-chordate animals and more than 30 phyla, many of which diverged >500 million years ago – and detailed knowledge of egg structure, function, and ecology is known for a comparatively small number of taxa. Thus, a comprehensive review of invertebrate egg structure is impossible, and our goal is to summarize larger patterns in egg structure among invertebrates, while discussing how these are exemplified in different phyla. Along with the variation associated with the vast taxonomic breadth of invertebrates, describing egg structure in invertebrates is also complicated by the variety of objects that are called 'egg' both in scientific and common usage across the animal kingdom. Strictly speaking, it is perhaps most correct to reserve the word 'egg' for a haploid, female gamete; however, the word is also frequently applied to oocytes that are meiotically arrested until fertilization, and it is also very common to apply it to protective structures that contain developing embryos. We will discuss both types of eggs here, starting with the egg cell or ovum.

Structure of the Egg Cell

To describe the basic structure of a metazoan ovum we will turn to one of the most-studied examples, the sea urchin (phylum Echinodermata, class Echinoidea) egg, which is described by Gilbert (2000) (Fig. 1). DNA in the egg is contained within a nucleus, and the cytoplasm contains organelles (ribosomes, mitochondria, nucleus, etc.), mRNA, tRNA, and other morphogenetic factors which determine polarity and regulate development. The cytoplasm also contains energy reserves for the developing embryo in the form of glycogen, protein, and lipid (often collectively referred to as 'yolk'). The cytoplasm is enclosed by an egg membrane containing cortical granules and a vitelline envelope that lifts off the egg when the cortical granules discharge at fertilization. The vitelline envelope is surrounded by a jelly coat which, in sea urchins, may contain pigment granules or other inclusions (Fig. 2). This basic structure holds across invertebrate phyla although there are many variations (described in Gilbert and Raunio (1997)). In the egg cells of one sponge species, for example, long radiating collagen fibers extend through the vitelline envelope and are retracted into the egg after fertilization; eggs of most species of chitons (phylum Mollusca, class Polyplacophora) are covered with small

projections called cupules; and the eggs of many crustaceans, as well as many terrestrial invertebrates, are surrounded by a protective hull called a chorion or shell (Fig. 2).

Egg cells are produced through the process of oogenesis, during which cells develop and are provisioned in the adult body. Oogenesis varies considerably among invertebrates, as does the structure and composition of the resulting egg cells. During oogenesis egg cells are provisioned with some combination of yolk granules or yolk platelets (through the process of vitellogenesis), and this yolk fuels the early stages of development. Many invertebrates have nurse cells which directly transfer cytoplasm to the developing egg, and in some cases nurse cells are phagocytosed directly and their remnants can be seen inside mature eggs. Species can be categorized by their characteristic amount and location of yolk within the egg. Isolecithal eggs have a small amount of yolk that is more-or-less evenly spread throughout the cell; in telolecithal eggs, the yolk is found predominantly at one pole; and in centrolecithal eggs, yolk is concentrated in the center. The location and amount of yolk in an egg is associated with both cleavage patterns and the length and type of development in invertebrates, a topic we will cover in more detail below. The location of yolk is also related to egg polarity, a phenomenon in which the animal and vegetal poles are determined prior to fertilization. While not all taxa show pre-fertilization polarity (for example members of the phylum Nematoda), many do, including molluscs, annelids, echinoderms, nemertean, and arthropods. In these groups the vegetal pole, or the side of the egg which cleaves more slowly, generally contains more yolk and is appears to be determined by the region of the egg surface which provides the physical connection to the ovarian wall.

Along with yolk, egg cells also contain the information necessary for development. This information comes in many forms including DNA, maternally-derived mRNAs, tRNA, and other morphogenetic factors. When present these morphogenetic determinants specify egg polarity and many aspects of cell fate. The egg can also contain transcripts of its own genome, particularly those genes associated with meiosis and fertilization. In taxa that depend on endosymbiotic relationships with microorganisms for obtaining energy, such as corals (Cnidaria, Anthozoa) or deep sea hydrothermal vent clams (Mollusca, Bivalvia), endosymbionts can be packaged into the egg and thus passed on to offspring, a process known as vertical transmission. Finally, egg cells can also contain specific maternally-supplied factors that protect the developing embryo from environmental stress, such as heat shock proteins and UV protectant proteins.

Types of Eggs

Primary Oocytes, Secondary Oocytes, Ova

Sea urchins are unusual among invertebrates (and animals in general) in that they complete meiosis in the ovary prior to fertilization and spawning; this is the exception rather than the rule. Members of most other phyla have been shown to arrest in metaphase I or II as primary or secondary oocytes (Fig. 3). In many taxa, the sperm enters the egg when it is an oocyte rather than a haploid ovum; sperm entry then triggers the completion of meiosis and maturation to an ovum, followed by fusion of the egg and sperm pronucleus. Release from meiotic arrest can also be a two-part process with a hormonal or external signal causing release from prophase I, which permits germinal vesicle breakdown, progression to metaphase I, and fertilization. The mechanisms underlying this variation and its evolutionary significance are not well understood; we include this information to demonstrate that the word egg (when referencing a single cell) is applied not just to haploid female gametes, but to female gametes at a wide variety of stages of maturation.

Embryonated Eggs

Besides egg cells and their associated coverings, the second type of structure that is called an egg in invertebrate biology is an embryo that is protected during development by a surrounding, maternally-produced structure or casing (Figs. 2(d) and 4). Examples

include the embryonated eggs of many molluscs, arthropods, platyhelminths, and terrestrial insects; embryos develop in these structures until they hatch as larvae or juveniles. Embryos inside eggs can receive post-oogenetic maternal provisioning in various ways, including extraembryonic yolk, albumen, and nurse eggs (non-developing or unfertilized egg cells that are packaged with the embryo). When embryonated eggs are attached to the substrate and/or contain multiple embryos, they are often called egg capsules. Embryonated eggs that are clustered together and share a common external gelatinous matrix are generally termed 'egg masses', as in the egg masses of nudibranch molluscs (Fig. 4(a) and (b)) and many polychaete worms; the term egg mass is also applied to clusters of egg capsules or gelatinous masses produced by the same parent, for example the benthic attached egg capsules of buccinid gastropods or cephalopods (e.g., squid eggs) and the egg masses of many insects and crustaceans (Fig. 4(c)).

Ecological and Evolutionary Aspects of Egg Structure

The structure of eggs is driven by selection on a number of different pre- and post-zygotic forces, and is intertwined with the evolutionary history, ecology, and life histories of individual species and taxa. We cannot cover more than a scattering of examples here, and there are cases where species do not fall cleanly into the categories below – e.g., there is not a perfect correspondence between spawning mode and degree of parental care. However, we define some generalities below and discuss how some common life history traits are related to egg structure.

Broadcast Spawners

Eggs (whether ova or oocytes) of many marine taxa are released directly into the water by the parent; for these broadcast-spawning taxa, eggs must be provided by the parent with all the materials and structures needed for successful exit from the parent, fertilization, and early development. Broadcast spawning is widely distributed across the metazoan phylogeny, and occurs in at least some members of many major and minor phyla, including (but not limited to) Cnidaria, Ctenophora, Mollusca, Annelida, Nemertea, and Echinodermata.

Accessory coats

One prominent feature of the broadcast-spawned eggs of many taxa are accessory structures that surround the egg and are shed early in development, including jelly coats, textured fertilization envelopes, follicle cells, and hulls (Podolsky, 2002). These accessory structures vary in structure and function. Accessory structures can provide physical protection to the ovum and early embryo; they may act as a barrier to entry by microbial or viral pathogens, or, by increasing the effective size of the egg, provide protection from predators. In taxa that are vulnerable to polyspermy, accessory coats can also act as a physical barrier that limits sperm contact and slows sperm entry speed to facilitate monospermic fertilization. Eggs can also experience shear stress while passing through the oviduct and gonopore during spawning; work with echinoderms suggests that the extracellular coats that are found on the eggs of some free-spawning taxa may protect the ovum or developing embryo from damage due to these shear forces (Thomas and Bolton, 1999). Accessory structures such as jelly coats may also be important in maintaining egg and embryo integrity in the extraparental environment, particularly in environments with strong, turbulent water movement.

One additional important function of accessory structures is to enhance sperm-egg encounters and fertilization success in the water column, where environments can often be sperm-limited due to turbulence, currents, or low population density (Levitan, 2002). Accessory structures can enhance fertilization in a number of ways: by releasing chemical compounds that facilitate fertilization through altering sperm physiology and function; by increasing the effective target size of the egg, thus raising the probability of sperm-egg contact; by directing sperm to particular areas of the egg; and by slowing the sinking rate or altering the buoyancy of eggs to keep them suspended in the water column where they are more likely to encounter sperm (Podolsky, 2002). Because accessory coats are generally constructed of less energy-rich materials than the egg itself, they can alter the physical properties of eggs (e.g., size, density) at a considerably lower energetic cost than a similar change to the properties of the egg itself.

Egg composition

In addition to providing protection from environmental stresses for the egg and developing zygote, in free-spawning taxa the contents of the egg must also provide sufficient energy and materials for the zygote to develop to independent feeding. The extent to which embryos and larvae are dependent on materials in the egg varies tremendously across taxa and even among closely related species, and the variation in egg structure among taxa is thought to reflect these requirements. Among broadcast spawners, many taxa have larvae that must feed in the plankton to acquire energy for growth and metamorphosis (planktotrophy), while in others, the egg and/or egg coverings contain sufficient material and energy for offspring to develop without feeding on particulate material (lecithotrophy). Within planktotrophy, there is a continuum from species with tiny eggs and long feeding developmental periods, to species that have comparatively large eggs and are facultative feeders (meaning they can feed, but do not need to). Lecithotrophs overall have larger eggs than planktotrophs, at least within taxa. This pattern occurs in many phyla but to date has been most extensively studied in echinoderms, from which most conclusions about the relationships between egg size, larval ecology, evolution, and physiology have been drawn.

Egg size is a frequently-measured and reported life history character that is often used as a proxy for egg energetic content and per-offspring maternal investment. Larger eggs generally contain more energy than small eggs; however, egg size is not always a good

Fig. 5 Scaling of egg energy with mass for planktotrophic (filled circles, dotted line) and lecithotrophic (open circles) echinoderms, showing that eggs of lecithotrophs are larger and more energy-rich, and that the scaling of egg energy to volume differs between the two groups. Modified with permission from **Fig. 1** of Moran, A.L., McAlister, J.S., Whitehill, E.A.G., 2013. Eggs as energy: Revisiting the scaling of egg size and energetic content among echinoderms. *The Biological Bulletin* 224 (3), 184–191.

predictor of energy content, particularly within species. Assumptions about how egg energy scales with size are incorporated into most models of invertebrate life history evolution that invoke tradeoffs between size and number of offspring or between per-offspring quality and offspring fitness; thus, an understanding of the nature of this scaling is crucial. The most comprehensive attempts to describe the scaling of egg size and egg energy have focused on echinoderms. In this group, two patterns are evident; total energy increases with egg size, and lecithotrophic species have both larger and more energy-rich eggs than planktotrophs (Jaekle, 1995). However, when egg energy was regressed on egg size for planktotrophs and lecithotrophs separately, the scaling exponent of this relationship is lower for planktotrophs (slope = 0.86x) than for lecithotrophs (slope = 1.02x) (**Fig. 5**). Thus, among lecithotrophs, egg energy density does not change significantly as egg size increases; in contrast, in planktotrophic species, large eggs are proportionately more energy-poor than small eggs. The mechanism for this pattern is not known, but in one genus of planktotrophic tropical urchins (*Echinometra*), the proportional composition of protein, lipid, and carbohydrate does not change with egg size; this suggests that larger eggs contain a higher proportion of water or other non-organic materials (Moran *et al.*, 2013). Thus, egg size in this group may have evolved not in response to fecundity-time tradeoffs, but in a context of selection for some other attribute like target size for sperm.

In general, among echinoderms, eggs of lecithotrophic species are enriched in lipids compared to planktotrophs. This is likely because the egg of lecithotrophic species must contain sufficient energy to fuel not just larval development, but also metamorphosis and some post-metamorphic development as well. Comparing within the starfish family Asterinidae, Prowse *et al.* (2008) showed that eggs of lecithotrophic species had higher proportions of energetic lipids (largely triacylglycerols) than did planktotrophs, and inferred this was due to a prolongation of the lipogenetic phase of oogenesis. Also within this family, the eggs of lecithotrophic species varied in their buoyancy such that eggs with higher proportions of lipid were more buoyant. Increased buoyancy could be a strategy to enhance fertilization success if gametes concentrate at the air-water interface. In contrast, one lecithotrophic species in the genus with large eggs also makes eggs that are comparatively lipid-poor and protein rich; this species develops on the benthos, and the added protein may function as a weight belt to reduce egg and larval buoyancy, permitting development to occur on the bottom. Thus, while overall it seems to be the case that developmental mode, egg size, and egg composition are correlated across taxa (at least within echinoderms), egg composition can also evolve in different directions under specific selection regimes that are unique to a particular species.

Embryonated Eggs and Parental Care

Internal fertilization

While many invertebrates are free-spawners, there are also many that have internal fertilization, either through spermcasting (when sperm are broadcast-spawned but eggs are retained in the female) or via copulation or other mechanisms for active sperm transfer. The dynamics of internal fertilization are poorly understood for most invertebrates, even model systems like *Drosophila* (Loppin *et al.*, 2015). Logically, however, an egg is less likely to experience sperm limitation when fertilization is internal; indeed, many invertebrates have mechanisms for sperm storage in the female reproductive system, and the sperm are used in a highly efficient manner to fertilize eggs. When sperm-egg encounters are under the control of the female reproductive system, or when females

copulate with multiple males or have behaviors that bring eggs and sperm into close proximity, eggs are unlikely to experience strong selection for traits that increase the probability of sperm-egg contact in free-spawners, such as larger size, large accessory coats, or the production of strong sperm attractants.

Egg capsules and egg masses

When eggs are no longer freely spawned into the environment, many of the protective and nutritive functions of the oocytes of free-spawners can be taken over by some type of parental care (either internal or, more frequently, external). Many invertebrates produce structures that contain the developing embryo, creating an embryonated egg. When the structures contain a single zygote, they are often called eggs (as in the eggs of insects and crustaceans); when multiple zygotes share a single structure, or when these structures are clustered together, they are generally called egg capsules or egg masses (as in many gastropods, cephalopods, flatworms, and annelids). Egg capsules and masses are found in a wide variety of taxa and are often structurally complex, consisting of tough leathery capsules or complex gelatinous matrixes around the zygote (Fig. 5) (Thorson, 1950). In some cases, components of the egg itself facilitate egg mass formation; in most marine crustaceans, for example, the vitelline membrane adheres to the abdomen of the mother, creating an egg mass inside a facultative brood chamber (Subramoniam, 2016). The function of egg masses is generally thought to be protective; for marine invertebrates, embryos that develop in benthic capsules can avoid advection and predation in the plankton, and for marine and terrestrial embryos alike the capsules can contain chemical defenses or provide protection from predation, parasitism, desiccation, UV, and other environmental stressors (Pechenik, 1979). The nature and composition of capsule coverings varies tremendously depending on environment; for example, the coverings around insect embryos must walk a fine line between desiccation resistance and permeability to oxygen, two functions that are essential for development but are in opposition to each other (Kambysellis *et al.*, 1999). Similarly, the egg mass jelly that surrounds embryos of many gastropods and annelids must provide physical protection to developing embryos while allowing diffusion of oxygen into the mass, leading to the evolution of elaborate egg masses with high surface areas and short diffusion distances (Moran and Woods, 2007).

Extraembryonic nutrition

Another opportunity afforded by encapsulation of zygotes is the provisioning of the embryo with extra-embryonic nutrition (EEN). EEN is found in a wide variety of invertebrates, particularly molluscs and annelids, and takes many forms including protein-rich fluid (albumen), extraembryonic yolk, non-developing eggs (nurse eggs, trophic eggs, or nutritive eggs), or even sibling embryos (adelphophagy). Like internal fertilization, the provisioning of eggs with EEN changes the selective environment acting on egg size and structure, because the embryo does not need to be entirely built by or fueled from materials in the egg. Thus, while the oocytes of lecithotrophic free-spawning taxa tend to be large and rich in lipids, large offspring can be produced by species with encapsulated development regardless of whether the oocytes are large and energy-rich or small and energy-poor; these two strategies exist on a continuum and the functional and adaptive consequences of maternal provisioning of intra- vs. extraembryonic nutrition are not known (Marko *et al.*, 2014). One interesting and long-standing question about nurse eggs is how they are specified; in some cases, trophic eggs are unfertilized ova, but in others they appear to be ova whose development is arrested (Perry and Roitberg, 2006). Understanding the maternal mechanisms that regulate development in trophic eggs may lead to new discoveries about the evolution of egg structure and provisioning across many types of invertebrates.

Conclusion

Invertebrates comprise all of metazoan diversity and metazoans inhabit and produce eggs in almost every habitat on Earth; thus, the diversity of structure in egg cells and egg coverings in the invertebrates is far too great to adequately summarize in a single chapter. Above we have briefly described egg structure in the best-understood system, the sea urchin egg; reviewed the list of different types of structures that are called eggs in the scientific literature on invertebrates; and described some of the major ecological and evolutionary contexts that shape egg structure and function. However, egg structure has been described for only a very small percentage of the existing diversity, and detailed observations of ultrastructure, biochemistry, and physiology are even rarer. It is our hope that the advent of more comprehensive and accurate invertebrate phylogenies, along with the development of modern molecular techniques for understanding egg physiology and function, the factors that shape the adaptive structure and function of eggs will be better understood.

Introduction

The term “oogenesis” or “ovogenesis” refers specifically to the transformation of oogonia into oocytes. In lower vertebrates, such as fish and amphibians, this process starts when oogonia enter into meiosis to become primary oocytes, and subsequently form a follicle when they are surrounded by somatic cells. Further growth of the oocyte mainly by the accumulation of large reserves of yolk (vitellogenesis), the hormone-induced meiosis resumption (oocyte maturation), and the release of the mature oocyte from the enveloping layer of somatic cells (ovulation), results in the production of a fertilizable egg. The main focus of this section, is on the early oogenic events including: the formation of oogonia, their transition into meiosis, and the first stages of oocyte development until the formation of the primary growth ovarian follicle.

Formation of Oogonia

Shortly after fertilization of the egg and during the early stage of embryogenesis, a small number of non-dividing primordial germ cells (PGCs) are produced, which will eventually divide through mitosis and colonize the genital ridge (Le Menn *et al.*, 2007). The PGCs colonizing the gonad stroma are relatively large, irregular in shape, with a rather large nucleus, and may exhibit temporary cytoplasm-filled projections of the cell (pseudopodia) indicative of their migratory status. The PGCs are bipotential cells capable of evolving into oogonia in females or into spermatogonia in males. The PGCs give rise to the recently discovered germline stem cells

Fig. 1 Schematic representation of the stages of oogenesis from premeiotic oogonia through the formation of the primary growth follicle in amphibians and teleosts. The progressive phases of meiosis and the formation of the Balbiani body are shown.

(GSCs), which reside in a lateral, anterior-posterior band at the ovary periphery termed the germinal zone where meiotic oocytes are generated (Elkouby and Mullins, 2017). The mechanisms through which GSCs are born from PGCs, and how their proliferation, self-renewal, and generation of subsequent mitotic cells and differentiating oocytes are just beginning to be understood. For example, it has been shown that GSCs specifically express the RNA-binding proteins Nanos 2 and 3, required for their maintenance and competence to generate oocytes.

The mechanism through which the GSCs differentiate into mitotic oogonia, the precursor cells of meiotic oocytes, are yet to be determined. It has been established, however, that the transformation involves structural changes within the GSCs, including the progressive increase in nuclear and cell size, as well as of the number of nuclear pores and organelles in the cytoplasm, and the differentiation of the nucleolus (Le Menn et al., 2007). During this transition, the electron dense material called "ciment" or germinal dense bodies, which constitute mitochondrial aggregates, as well as the "nuage" or germ granules (see below), both also present in PGCs, increase in size and number. Once formed, the oogonia proliferate through a variable number of cell divisions, dependent upon the species, and form germline cysts within the germinal epithelium. Prior to the initiation of meiosis, the oogonia multiply rapidly, and remain interconnected by cytoplasmic bridges as a result of incomplete cytokinesis and abscission between daughter cells (Fig. 1). The cysts are separated by the stroma by a basement lamina secreted by somatic (pre-granulosa) cells. In some teleosts, however, oogonia may also become isolated and surrounded by a few pre-granulosa cells. This organization in germline cysts, in which oogonia are interconnected by cytoplasmic bridges, is thought to synchronize the development of individual oocytes (Elkouby and Mullins, 2017). In mammals, the transfer of cytoplasmic contents between cyst oocytes is thought to lead to the growth of one oocyte and subsequent death of the other, such that the majority of oocytes do not develop into primordial follicles. In the African clawed frog (*Xenopus laevis*) and the teleost medaka (*Oryzias latipes*), however, only a few cells in the mitotic cyst or its neighbour undergo apoptosis (Elkouby and Mullins, 2017).

The hormonal mechanisms controlling oogonial proliferation in fish and amphibians are poorly known, although early studies on hypophysectomized and unilaterally ovariectomized teleosts suggest that pituitary gonadotropins, especially follicle-stimulating hormone (Fsh), can increase oogonial proliferation (Lubzens et al., 2010). This mechanism is likely indirect through the local release of sex steroid hormones since studies on cyprinids and salmonids have shown that ovarian estrogens, such as 17β -estradiol, can induce the mitotic activity of oogonia. As observed in mammals, growth factors could also promote oogonia proliferation, such as the gonadal soma-derived growth factor (Gsdf), a cytokine belonging to the transforming growth factor- β (Tgf β) superfamily which has been involved in spermatogonial proliferation in the testes and is detected in the supporting cells surrounding oogonia and oocytes in several teleosts. The mechanisms regulating steroid and growth factor production in the fish and amphibian germinal epithelium are yet unknown, although the Fsh-mediated secretion of these factors by the pre-granulosa cells in close vicinity to oogonia might play a role.

Transformation of Oogonia into Primary Oocytes

The transition from oogonium to a primary oocyte is primarily characterized by the initiation of the first meiotic division, before leaving the germline cyst. The differentiation of oocytes is also accompanied by other key developmental events, such as the acquisition of cell polarity and the formation of the Balbiani body, and changes in cellular organization from cyst to follicles of individual oocytes.

Meiosis Initiation

Within the cyst, each oogonium is a diploid cell, with a nucleus containing two copies of each chromosome, called homologs, one from the father and one from the mother. During the interphase following the last mitotic division of a diploid oogonium and preceding the first meiotic division of the primary oocyte, each homolog is duplicated by DNA replication (pre-leptotene), giving rise to a pair of identical chromatids, known as a sister chromatid pair (Fig. 1). These homologous chromosomes pair and begin to condense (leptotene, zygotene), and subsequently shorten and thicken to form the synaptonemal complex (pachytene), when homologous recombination, including chromosomal crossover (crossing over), occurs. During the leptotene stage, chromosomes attach to the nuclear envelope via their telomeres, which then rotate on the envelope, tumbling entire chromosomes inside the nucleus, and enabling their homology searches for pairing (Elkouby and Mullins, 2017). This mechanism eventually clusters the telomeres to one side of the nuclear envelope, with the free looping ends of their chromosomes facing the opposite side, at the zygotene stage (Fig. 1). This polarized organization is called the zygotene chromosomal bouquet, thought to help stabilize chromosomal synapsis, which is regulated by centrosome-based microtubules in the cytoplasm that connect to the telomeres via Sun/KASH proteins spanning the two membranes of the nuclear envelope (Elkouby and Mullins, 2017). Finally, during the diplotene stage the chromosomes take on a 'lampbrush' configuration in which large chromatin loops extended laterally allowing the active transcription of heterogeneous RNA, which adds to the ribosomal RNA provided by the multiple nucleoli. Most of the former RNA is processed into poly(A)-containing RNA, the so-called "maternal RNA", as it moves from the germinal vesicle into the cytoplasm where it becomes asymmetrically distributed (see below). Arrested in late diplotene of the first meiotic prophase, the oocyte then begins an extensive period of growth concomitant with the differentiation of its follicular components. This is generally called the "perinucleolus stage of primary oocyte growth".

In teleosts and amphibians, the hormonal signals triggering meiosis in oogonia are not well known. In mammals, retinoic acid (RA) signaling has been established as a major meiosis inducer. In zebrafish (*Danio rerio*), both the RA-synthesizing enzyme aldehyde dehydrogenase 1 and RA-degradating enzyme Cyp26 Cytochrome P450 have been found to be expressed in gonadal somatic cells, suggesting that RA signaling might also play a role in the onset of meiosis in teleosts (Elkouby and Mullins, 2017). However, recent studies *in vivo* and *in vitro* using long-term explant culture systems in cyprinid and salmonid teleosts have implicated the progestin 17,20 β -dihydroxy-4-pregnen-3-one (17,20 β P) in the entry into meiosis of oogonia, as well as of spermatogonia in the testis. The roles of 17,20 β P in teleosts and of progesterone in amphibians as the major hormonal signals for the resumption of meiosis during oocyte maturation are well established, and therefore these findings may indicate that 17,20 β P could control meiosis at different times during oocyte development in teleosts. However, the factors and mechanisms regulating steroid production at this time are unknown. In some teleosts, the onset of meiosis has been linked to the expression of insulin-like growth factor-I (Igf-I) in somatic cells and oocytes, but the mechanisms through which IGF-I could stimulate meiosis are not known.

Meiotic Arrest

As mentioned above, meiosis in early oocytes is arrested in the prophase of the first meiotic division, and prophase arrested oocytes proceed throughout the entire period of oocyte growth until the oocyte maturation stage, when oocytes resume meiosis and subsequently arrest again in metaphase of meiosis II. Arrest of meiosis I occurs in all vertebrates during oogenesis, and there is broad consensus that this process is maintained by high levels of cyclic adenosine monophosphate (cAMP) in the oocyte, which activates the enzyme protein kinase A.

In teleosts and amphibians, several mechanisms have been proposed to maintain high levels of cAMP in oocytes. One long-standing hypothesis is that cAMP produced in the surrounding follicular (granulosa) cells diffuses to the oocyte through gap junctions, which are aggregates of intercellular channels established between the oocyte and the granulosa cells that permit direct cell-cell transfer of ions and small molecules, such as the cAMP. This mechanism however might be more relevant in completely formed ovarian follicles than in primordial follicles in which the structures for cell-cell interaction between oocyte and granulosa cells are still in the course of being developed.

More recently the roles of a stimulatory G protein α subunit ($G_{\alpha s}$)-coupled G protein-coupled receptor (GPCR), such as GPR185 in amphibians, and the $G_{\alpha s}$ -coupled estrogen membrane receptor GPR30 in teleosts, have been proposed as mechanisms that maintain high levels of cAMP and oocyte meiotic arrest (Ríos-Cardona *et al.*, 2008; Thomas, 2017) (Fig. 2). Constitutive or estrogen activation of GPR185 and GPR30, respectively, leads to the stimulation of the adenylyl cyclase, which results in the increase of the intracellular concentration of cAMP. Activation of the GPR30 in teleost oocytes can also stimulate the $G\beta\gamma$ subunit signaling resulting in the activation of the Src family of protein tyrosine kinases followed by the up-regulation of matrix metalloproteinase (MMP), ultimately leading to release of heparan-bound epidermal growth factor (EGF) (Thomas, 2017). The EGF can then bind to the EGF receptor (EGFR) at the oocyte surface promoting mitogen activated protein kinases (MAPKs) signaling, phosphorylation of

Fig. 2 Proposed model of the maintenance of oocyte meiotic arrest in amphibians and teleosts by constitutive or estrogen-activated G protein-coupled receptors (GPRs). In teleosts, the role of the epidermal growth factor receptor (EGFR) and its regulation by the matrix metalloproteinase (MMP) and the progesterone receptor membrane component 1 (PGRMC1) is also indicated. Modified from Thomas, P., 2017. Role of G-protein-coupled estrogen receptor (GPER/GPR30) in maintenance of meiotic arrest in fish oocytes. *Journal of Steroid Biochemistry and Molecular Biology* 167, 153–161.

extracellular-related kinase 1 and 2 (Erk1/2), and the maintenance of meiotic arrest. Recent studies also indicate that progesterone receptor membrane component 1 (PGRMC1) plays a crucial role in regulating the expression of the EGFR; that in turn might influence the inhibitory effect of estrogens on resumption of meiosis through GPER (Thomas, 2017). In teleosts, the adenylyl cyclase-activating polypeptide (PACAP) is another cAMP modulating paracrine system that might help to maintain meiotic arrest, although this mechanism has been less investigated.

The Balbiani Body and Oocyte Polarization

A rather prominent feature during the differentiation of the primary oocyte is the formation of the Balbiani body (Bb), also known as yolk nucleus/body/complex, vitelline nucleus/body, mitochondrial cloud/mass/aggregate, or sponge body (Kloc *et al.*, 2014). The Bb is an aggregate of mRNA-protein (mRNP) and mitochondria that initially forms in the cytoplasm adjacent to the nucleus of zygotene stage oocytes, and then localizes to the oocyte cortex, where it dissociates at the later stages of cortical alveoli and vitellogenesis. The movement of the Bb to the oocyte cortex, its disassembling and docking of its contents in the membrane defines the vegetal pole of the oocyte, and therefore the Bb first establishes the definitive animal-vegetal axis of the oocyte, which lays the foundation for the embryonic body plan (Elkouby and Mullins, 2017).

Inside or outside of the Bb, oocytes also accumulate granulo-fibrillar non-membrane-bound material, known as the nuage, which plays a role in the germ plasm pathway (Kloc *et al.*, 2014). The germ plasm is constituted by maternally inherited germ cell determinants in female germ cells which is required for the specification and maintenance of germ cell fate during embryonic development. Perinuclear nuage contains ribonucleoproteins implicated in diverse RNA metabolism, including components of a gonad-specific RNA silencing pathway, the piwi-interacting RNA (piRNA) pathway, which is involved in the protection of the genome against deleterious selfish genetic elements such as transposons. Nuage granules also contain many proteins that bear a Tud domain, a small 50–55 amino acid β -barrel module which forms an aromatic cage that interacts with methylated amino acids, lysines or arginines of target proteins, including Piwi family proteins (Gao and Arkov, 2013). In zebrafish, the Tud domain proteins have been shown to play crucial roles in germ granule assembly.

The Bb forms the pathway for the delivery of mRNPs granules to the vegetal pole of the oocyte, while other mRNAs are recruited later to the defined vegetal pole, which is known as the “late pathway” (Escobar-Aguirre *et al.*, 2017). In addition to the germ plasm components, the zebrafish Bb contains proteins involved in mRNAs and mRNPs aggregation, such as Bucky ball (Buc) (see below), and dorsal determinants and dorsalizing machinery mRNAs (Escobar-Aguirre *et al.*, 2017). In *X. laevis*, the mRNAs of the Bb and/or Bb-derived germ plasm include RNA binding proteins, mRNAs encoding proteins involved in primordial germ cell migration, mRNAs encoding proteins implicated in scaffolding and/or recruitment of germ plasm components, and non-coding RNAs (Kloc *et al.*, 2014). The proteins identified in *X. laevis* Bb and/or Bb-derived germ plasm can be classified into translational repressors, anti-transposon factors, germinal granule assembly and maintenance factors, cell cycle regulators and proteins involved in RNA transport and localization (Kloc *et al.*, 2014).

Very little is known about the molecular mechanisms controlling Bb formation, its cortical localization, and its disassembly and cortical tethering of its mRNP cargo. In zebrafish, two genes, *bucky ball* (*buc*), which encodes an intrinsically disordered protein, and microtubule actin cross-linking factor 1 (*macf1*), have been identified that can regulate some of these processes (Escobar-Aguirre

et al., 2017). Buc, and the *X. laevis* homolog Xvelo, are the only known proteins required for Bb formation, and it is believed that they form a scaffolding phase-separating lattice in Bb granules that aggregates mRNAs and mRNPs during Bb formation. The Macf1 protein is a member of the spectraplakins family, and may mediate microtubule and actin connections to localize the Bb to the oocyte cortex and mediate its disassembling.

Recent studies in zebrafish have revealed that the nuclear polarity resulting from the chromosomal bouquet at the zygote stage is also involved in Bb formation upstream to the Bucky ball protein (Elkouby and Mullins, 2017). In these studies, it has been shown that microtubules are concomitantly required to cluster the telomeres of the bouquet and localize the Bb mitochondrial precursors, demonstrating that these nuclear and cytoplasmic events are mechanistically coordinated. Therefore, the bouquet stage centrosome functions as a global cellular organizer that couples meiotic events with oocyte patterning, which has been termed the meiotic-vegetal center or centrosome organizing center (Elkouby and Mullins, 2017).

Ovarian Folliculogenesis and Primary Oocyte Growth

Before leaving the germinal ridge, a single layer of pre-granulosa cells initially surrounds the entire nest of early meiotic oocytes. As the cells in the nest cellularize, the cyst structure of the oocyte is gradually broken by the invagination of somatic cells and, finally, the oocyte becomes a single cell surrounded by a sheath of squamous granulosa cells, which is known as the primary growth follicle (Le Menn *et al.*, 2007). The granulosa cells will complete the secretion of the basement lamina from their basal membrane, outside of which multilayers of unorganized meso-epithelial cells will constitute the thecal layer, or theca, irrigated by numerous blood vessels. At the same time, the oolemma separates from some areas of the apical granulosa cell surface, and the intervening space is filled with an extra-oocyte matrix that will become the vitelline envelope (zona pellucida) separating the oocyte and the granulosa epithelium. Later in follicle development, the granulosa cells will gradually increase in height to become more cuboidal and separate from each other to form intercellular spaces.

During ovarian follicle formation, granulosa cells surrounding the oocyte are connected through gap junctions and by a number of typical junction complexes, such as desmosomes and tight (occluding) junctions. In addition, cytoplasmic projections from the granulosa cells and oocyte, which will become true microvilli that cross the vitelline envelope in later developmental stages, make focal contact, and these connections will be maintained throughout oocyte growth. Gap junctions are formed between the oocyte and granulosa cells, which allow chemical communication, as well as other cell contact structures, such as junction complexes resembling adhering junctions, which contain α - and β -catenin and E-cadherin-like molecules. Interestingly, β -catenin is also accumulated in the vegetal pole of amphibian oocytes, and both in teleosts and amphibians is a key effector of the Wnt/ β -catenin signaling regulating the transcription of genes required for the establishment of the overall body plan patterning during embryogenesis (St Amand and Klymkowsky, 2001; Hüsken and Carl, 2013).

Several oocyte-expressed growth factors, such as growth/differentiation factor 9 (Gdf9) and bone morphogenetic factor 15 (Bmp15), both of which play important roles in early ovarian follicle growth in mammals, have been implicated in primary ovarian follicle development in teleosts and amphibians. However, no experimental evidence exists on their functional role during early oogenesis. Only in zebrafish has it recently been shown that Bmp15 can regulate the expression of estrogen producing enzymes in the granulosa cells, thus contributing to female sex determination (Dranow *et al.*, 2016).

Control of Gene Expression in Primary Growth Oocytes

When the follicle starts to form, the synaptonemal organization of the oocyte nucleus is de-structured by disassembling the lateral protein axes of the ladder-like central core (Le Menn *et al.*, 2007). The lampbrush chromosome structure appears and each sister chromatid pair is highly active in RNA synthesis, due to the double amount of DNA, compared to somatic cells. At this stage, the nucleoli increase due to a huge amplification of the nucleolar organizer genes, and the nucleus is then generally characterized by a large central nucleolus and numerous smaller nucleoli.

In addition to the accumulation of maternal RNAs important for further embryo development mentioned above, the primary oocyte also initiates the transcription of several genes with important roles during follicle formation, oocyte growth and maturation, and in marine teleosts producing pelagic (floating) eggs, during oocyte hydration. These transcripts include proteins associated with vitellogenin (the major precursor of yolk proteins in the oocyte) and lipid uptake, such as the vitellogenin receptors, some of the zona pellucida glycoproteins that will form the nascent vitelline envelope, cysteine proteases such as cathepsins which will process vitellogenin-derived yolk proteins during oocyte growth and maturation, cell cycle proteins involved in meiosis resumption, molecular chaperone proteins such as heat shock protein 40, metal binding proteins such as ferritin, and water channel proteins (aquaporins) which will facilitate water uptake into the oocyte (hydration) during meiotic maturation prior to ovulation (Guzmán *et al.*, 2014; Cerdà *et al.*, 2017).

The endocrine pathways controlling gene expression in primary oocytes are largely unknown. However, studies on the transcriptional control of one of the oocyte aquaporins (Aqp1ab) in the marine teleost gilthead seabream (*Sparus aurata*) have revealed that this mechanism is dependent on the classical nuclear progesterone receptor (Pgr), which is expressed in the cytoplasm of oogonia and the nucleus of primary oocytes and can bind to the aquaporin gene promoter thus activating *aqp1ab* gene transcription (Cerdà *et al.*, 2017). In this model, the Pgr is activated by the progesterone 17,20 β P, produced by primordial granulosa cells associated to primary oocytes in response to Fsh, which upregulates the expression of steroidogenic enzymes involved in progesterone synthesis and

Fig. 3 Proposed model for the endocrine pathway involved in aquaporin-1ab (*aqp1ab*) transcriptional regulation in gilthead seabream primary growth oocytes. The scheme depicts the Fsh receptor (Fshr)-mediated progestin (17,20bP) synthesis and subsequent activation of *aqp1ab* transcription through the nuclear progestin receptor (Pgr). At the primary growth stage, activation of the Fshr in granulosa cells triggers 17,20bP production through the upregulation of the P450c17-II (Cyp17a2)/20b-hydroxysteroid dehydrogenase (Cbr1) steroidogenic pathway in granulosa cells. Binding of 17,20bP to Pgr activates the receptor, which promotes transcription likely through interaction with the *aqp1ab* proximal gene promoter. Modified from Zapater, C., Chauvigné, F., Tingaud-Sequeira, A., Finn, R.N., Cerdà, J., 2013. Primary oocyte transcriptional activation of *aqp1ab* by the nuclear progestin receptor determines the pelagic egg phenotype of marine teleosts. *Developmental Biology* 15, 377 (2):345–362.

downregulates the major enzymes responsible for estrogen synthesis, resulting in an enhanced production of 17,20bP in the granulosa cells (Fig. 3). These findings suggest that that Fsh/progestin/Pgr signaling pathway might also regulate the transcription of other genes in the primary oocyte of lower vertebrates, similarly to the action of the progesterone-activated PGR during primordial follicle assembly in mammals. However future studies are necessary to demonstrate this hypothesis.

Introduction

Across species, the release of a mature healthy egg for fertilization is the center of the entire reproductive process. From the time of embryonic development till fertilization, the oocyte undergoes several stop-and-go periods which are tightly regulated throughout the reproductive cycle. Oocytes undergo first meiotic progression during embryonic development, and at the time of birth, they become arrested in the prophase stage. This meiotic arrest of oocytes is maintained until shortly before ovulation, when resumption of meiosis occurs and there is progression to metaphase II (MII), a process commonly termed *oocyte maturation*. Following resumption of meiosis I, there is organized disassembly of the nuclear envelope (germinal vesicle, GV) referred to as germinal vesicle breakdown (GVBD), followed by chromosome condensation, spindle formation and extrusion of the first polar body. Thereafter, the oocyte enters meiosis II and again gets arrested at metaphase II stage until fertilization. Upon fertilization, the oocyte resumes meiosis II extrudes the second polar body, thereby completing maturation (Dekel, 1995; Eppig *et al.*, 2004a,b). Oocyte maturation is one of the major steps for the oocyte to attain competence for successful fertilization and subsequent embryonic development. Acquisition of this developmental competence of the oocyte involves multiple factors regulated by different signaling pathways at various stages prior to fertilization (Jones, 2004; Mehlmann, 2005). While some crucial components of the signaling pathways involved in oocyte maturation are conserved from amphibians to mammals, there exists significant species-specific differences. This article highlights the differences in oocyte maturation among species and compares the various signaling pathways and underlying intracellular mechanisms involved in maintaining the meiotic arrest, regulation of oocyte maturation and ovulation across species.

Primary Meiotic Arrest

The segregation of the germ cell from the somatic lineage occurs very early during development in both invertebrates and vertebrates. Once the primordial germ cells (PGC) get committed to the germ cell lineage and enter meiosis, they progress to prophase I, where the first meiotic cycle is then arrested. This primary meiotic arrest occurs in all organisms considered in this article. The potential evolutionary rationale behind this highly conserved arrest (Mira, 1998) is based on three non-exclusive hypotheses. First, the “mutational hypothesis” suggests that the occurrence of prophase I arrest, early during meiosis to ensure that oocytes are made before division or prior to environmental perturbations causing DNA damage. This ensures that oocytes are as close to the “master-copy” as possible. The second “repair hypothesis” elucidates that by arresting at this stage when sister chromatids are present and held tightly together, the sister chromatid can be used as an ideal template to repair any DNA damage that arises. Lastly, an interesting “minimize conflict” hypothesis proposes that some type of inter-gamete competition may exist and arresting at prophase I ensures that all oocytes have four copies of each gene, discouraging the selection of oocytes based on genetic components solely useful to outcompete siblings instead of long-term offspring survival. Whether any or all of the above hypotheses are true or not is debatable, but the prophase I meiotic arrest is highly conserved from *C. elegans* and *Drosophila* to humans, and this arrest is critical to the oocyte growth and future embryonic development. However, the molecular means by which this arrest is maintained does differ somewhat (Sagata, 1998).

In 1935, Pincus and Enzmann were the first to show that the removal of prophase I arrested rabbit oocytes from their follicular environment resulted in the spontaneous resumption of meiosis (Pincus and Enzmann, 1935). This finding supported a model where the surrounding somatic cells regulated maintenance of the prophase I meiotic arrest. The prophase I meiotic arrest is maintained by several similar mechanisms across different species with some distinct differences. In general, in mouse, *Xenopus*, human, porcine, bovine, chicken, and *C. elegans* the primary meiotic arrest is maintained by synthesis of inhibitory factors in the somatic cells surrounding the oocyte and within the oocyte itself that result in CDK1/CDC2 inactivation in the oocyte (Parker and Piwnicka-Worms, 1992; Bilodeau *et al.*, 1993; Govindan *et al.*, 2006; Shimada, 2012; Cook, 2017). One of the primary factors involved in maintaining the oocyte in the prophase I meiotic arrest is cAMP. In mammals and *Xenopus*, cAMP is synthesized both in the oocyte and the surrounding cumulus cells where it is continuously transported into the oocyte by gap junctions (Shimada, 2012). In contrast, in the *C. elegans* oocyte, instead of direct transport of cAMP in the oocyte, the somatic gonadal sheath cells synthesize G_g/α and transport it into the developing oocytes, which activates adenylate cyclase and elevates cAMP levels (Govindan *et al.*, 2006, 2009). This differs slightly in mammalian oocytes where the constitutively active GS-linked receptors, GPR3 and GPR12, stimulate adenylate cyclase to make cAMP (Arur, 2017). The resulting high levels of cAMP in the oocytes activates the cAMP-dependent kinase, PKA, which then phosphorylates and activates Wee kinase family members, including the oocyte-specific Wee1B kinase (Han *et al.*, 2005). Wee kinase family members include Wee1 and Myt kinases which can phosphorylate and inactivate CDK1/CDC20 at two highly-conserved residues, Thr14 and Thr15 (Parker and Piwnicka-Worms, 1992; Fattaey and Booher, 1997). This CDK1/CDC20 inactivation prevents activation of the maturation promoting factor (MPF; a complex consisting of cyclin B and CDK1/CDC20) and continually holds the oocytes in prophase I arrest (Han *et al.*, 2005). In bovine, it appears that cAMP is degraded to AMP which activates adenosine monophosphate-activated protein kinase (AMPK), and although this is necessary for meiotic arrest, it is currently unknown how AMPK activity relates to low MPF which is also necessary to maintain the prophase I

arrest (Bilodeau-Goeseels, 2011). There is evidence in mouse, *Xenopus*, human, and porcine that activation of Wee kinases and inhibition of CDK1/CDC20 is a conserved mechanism, although whether the target kinase is Wee1 or Myt differs between organisms (Han *et al.*, 2005; Shimaoka *et al.*, 2009; Shimada, 2012). Despite being a powerful model organism, surprisingly little is known regarding mechanisms for maintenance of the prophase I arrest in *Drosophila*. It is clear that the *Drosophila* oocyte accumulates the CDK1-inhibitor, Dap, which keeps it in S-phase whereas the nurse cells have low levels of Dap and being multiple rounds of endoduplication and as a result, become highly polyploid (Hong *et al.*, 2003). An unique feature of the *Drosophila* arrest is that the surrounding somatic cells (nurse cells) are dispensable for maintenance of the prophase I arrest, which is quite interesting considering the important role nurse cells have in oocyte determination and growth and that they are also directly connected to the oocyte by cytoplasmic bridges (Bohrmann and Zimmermann, 2008). In summation, although the prophase I arrest is highly conserved across all organisms discussed, the mechanisms employed to maintain it are quite different across species including the importance of the surrounding somatic cells and specific downstream targets that modulate CDK and MPF activity.

Meiotic Resumption/Maturation

While the prophase I arrest is highly conserved, the resumption of meiosis in response to an extracellular stimulus varies across species. For example, in *C. elegans*, major sperm protein (MSP) has been identified as the hormonal stimulus that stimulates both meiotic resumption as well as somatic gonadal sheath cell contraction to move oocytes towards the proximal gonad (McCarter *et al.*, 1999; Miller *et al.*, 2001). *Xenopus* meiotic resumption occurs in response to progesterone which causes a rapid drop in intracellular cAMP levels in the oocyte (Maller *et al.*, 1979). In mammals and chickens, an endogenous luteinizing hormone (LH) surge stimulates meiotic resumption (Seibel *et al.*, 1982; Jaffe and Norris, 2010; Cook, 2017). In mouse oocytes, inactive MPF is present throughout ooplasm and the LH surge causes a rapid decrease in cellular cAMP levels which subsequently decreases PKA and Wee1b activity, and activates CDK1 (Eppig *et al.*, 2004a,b). Androgens (Hammes, 2004) have also been shown to induce meiotic resumption in *Xenopus* (Lutz *et al.*, 2001) and mouse oocytes (Gill *et al.*, 2004). Unlike rodents, bovine and porcine oocyte have very low levels of cyclin B throughout the ooplasm and require active translation of the MPF regulatory subunit to resume meiosis (Naito *et al.*, 1995; Levesque and Sirard, 1996). The signal that initiates meiotic resumption in *Drosophila* remains unknown, but MPF activation is also necessary (Von Stetina and Orr-Weaver, 2011).

After MPF activation and subsequent meiotic resumption, oocytes proceed through several physiological processes in preparation for fertilization. MPF is the master regulator during M phase, and active MPF phosphorylates multiple target proteins which mediate nuclear envelope breakdown (NEBD) also referred as germinal vesicle breakdown (GVBD), chromatin remodeling, and spindle formation (Sagata, 1998). In all species discussed in this article, oocytes do not resume transcription during meiotic maturation, highlighting the importance of maternal mRNA polyadenylation, stability, and degradation (De La Fuente *et al.*, 2004). MPF activates ERK1/2, which then phosphorylates and activates CPEB (Sha *et al.*, 2017), which is a sequence-specific RNA-binding protein that regulates polyadenylation-induced translation. Active CPEB polyadenylates specific mRNAs throughout the ooplasm for targeted translation even as global translation rates are decreasing during meiotic maturation (Schultz *et al.*, 1978; Sha *et al.*, 2017). Unlike mitosis, during meiosis, chromosomes remain tightly condensed as oocytes progress from meiosis I to meiosis II. As mammalian, *Xenopus*, and chicken oocytes progress through meiosis I, they give off a small polar body (PBI), and then continue to metaphase of meiosis II (Dumont, 1972; Mehlmann, 2005; Cook, 2017). Interestingly, in *C. elegans*, meiotic maturation first involves downregulation of MPK-1 (ERK) and later cellular levels rebound to ensure correct maturation of the oocyte, indicating MPK-1 has a dual purpose specific to *C. elegans* oocytes (Arur, 2017). In *Drosophila*, a protein called ENDOS, which is a member of a group of small proteins called α -Endosulfines with wide expression but largely of unknown functions is believed to be involved in meiotic maturation (Von Stetina and Orr-Weaver, 2011). ENDOS encodes a phosphoprotein that regulates all aspect of meiotic maturation, most likely through regulating MPF activity, although what controls activation of ENDOS remains unknown (Von Stetina *et al.*, 2008). Also unique to *Drosophila* is that there is no extrusion of first or second polar body during meiosis (Page and Orr-Weaver, 1997). Taken together, while the organisms discussed here have some distinct features, the critical role of MPF in regulating meiotic maturation is highly conserved.

Secondary Meiotic Arrest

With respect to the secondary meiotic arrest, *C. elegans* and *Drosophila* stand out as very different from the other animals discussed in this article. Unlike the other gonochoristic species in this article, the hermaphroditic *C. elegans* utilizes the major sperm protein (MSP) hormone as a signal for meiotic maturation, thereby ensuring the presence of sperm for fertilization and bypassing the need for a second meiotic arrest (Yamamoto *et al.*, 2006). *C. elegans* MSPs are the most abundant proteins in sperm, where they function as intracellular cytoskeletal proteins and secreted hormones. Secreted MSPs bind to multiple receptors on oocyte and ovarian sheath cell surfaces to activate MPK-1 and induce oocyte maturation and sheath contraction (Yang *et al.*, 2010). The coupling of meiotic resumption and meiotic maturation directly to sperm-sensing confers a selective advantage in *C. elegans* as they continually produce oocytes when sperm is present, and therefore are able to save energy by not producing the metabolically-costly oocytes when sperm is not available (Yamamoto *et al.*, 2006). In *Drosophila*, oocytes arrest at metaphase I and MPF is critically important in maintenance of the second meiotic arrest. For meiotic completion, Cyclin B must be degraded.

The completion of meiosis in *Drosophila* is sperm-independent and results from the mechanical pressure on the oocyte as it passes through the oviduct. It has been proposed that lack of coupling of fertilization to meiotic completion is a remnant from a time when *Drosophila* was able to asexually reproduce. Although most species of *Drosophila* do not support parthenogenic development, some species such as *Drosophila mercatorum* have viable progeny from parthenogenically-activated oocytes (Eisman and Kaufman, 2007; Von Stetina and Orr-Weaver, 2011).

In mammals, chickens, and *Xenopus*, the second meiotic arrest occurs at metaphase of meiosis II (MII) due to the cytostatic factor (CSF) (Nishiyama *et al.*, 2010; Nakamura *et al.*, 2013). CSF was first discovered in *Rana pipiens* where it was shown that injecting the cytoplasm from a MII oocyte halts cell division in a 2-cell blastomere, indicating some transferable cytoplasmic factor in MII oocytes that is responsible for the MII arrest (Masui, 1974). Ultimately, the Mos/MEK/MAPK/Rsk signaling cascade (MOS is a germ cell-specific Raf) has been identified as the CSF in *Xenopus* (Nishiyama *et al.*, 2010). The downstream effect of this cascade is activation of Emi-related protein 1 (ERP1), which is an inhibitor of the anaphase-promoting complex/cyclosome (APC/C), the result of which is maintaining the MII arrest until fertilization occurs (Schmidt *et al.*, 2005). In mice, the CSF also involves MOS and MAPK but not Rsk, although activation of ERP1 is still the end result (Nishiyama *et al.*, 2010). In bovine, porcine and human oocytes, MAPK is also required for the MII arrest, and although the downstream targets are likely similar to mouse or *Xenopus*, these have not been directly assayed (Sun *et al.*, 1999; Gordo *et al.*, 2001; Tatemoto and Muto, 2001). This MII arrest is carefully coupled to fertilization as sperm entry causes a Ca^{2+} wave throughout the oocyte, resulting in the destruction of ERP1, followed by destruction of cyclin B, activation of the APC/C, and finally initiation of zygotic development. Coupling the completion of meiosis with fertilization ensures that the maternal and paternal pronuclei form at the same time and will be in sync upon entry into S phase.

Ovulation

Ovulation is the release of the growing oocyte from the ovary into the reproductive tract for fertilization. Achievement of successful ovulation is carefully orchestrated by the mural granulosa cells responding to the LH surge by activation of their LH-receptor (Russell and Robker, 2007). In all animals discussed in this article the structure receiving the ovulated oocyte is called the oviduct, except in *C. elegans* where oocytes move into the spermatheca. The rate and efficiency of ovulation is a major factor in successful reproduction as it ensures that the oocyte is at the right time and place for successful fertilization. In *Xenopus*, mouse, bovine, and porcine normal ovulation is controlled by the release of luteinizing hormone and follicle-stimulating hormone from the pituitary gland. An important consideration when studying ovulation is whether the species of interest is a mono or poly-ovulator. The majority of the time, bovine and humans are both mono-ovulators whereas porcine and mice are poly-ovulators (Hunter *et al.*, 2004). Distinct from all other animals is *Xenopus* ovulation involving the expulsion of hundreds of mature oocytes into an aquatic environment for external fertilization.

In addition to the unique external fertilization in *Xenopus* discussed above, *C. elegans* and *Drosophila*, and chickens have some distinct ovulation features. In *C. elegans*, the oocyte ovulates into a specialized structure, the spermatheca, is rapidly fertilized and then moves into the uterus within 4 min of ovulation (Kim *et al.*, 2013). In *Drosophila*, surrounding somatic secretory cells in the reproductive tract secrete HR39 (a nuclear hormone receptor steroidogenic factor 1, SF1; NR5A1-related *Drosophila* nuclear hormone receptor), which stimulates ovulation, in addition to other proteins necessary for sperm storage in the reproductive tract after mating (Sun and Spradling, 2013). During *Drosophila* ovulation, only one of the many mature oocytes in the ovaries is released into the oviduct. Furthermore, in *Drosophila*, ovulation serves the dual-purpose of moving the oocyte forward and stimulating meiotic resumption (Von Stetina and Orr-Weaver, 2011). A common feature between *Drosophila*, *C. elegans*, and the chicken is that the female (or hermaphrodite in *C. elegans*) has the ability to store sperm for an extended period of time for fertilization of individually ovulated oocytes in an assembly-line fashion. After a single mating event in flies, females store the sperm and can remain fertile for up to two weeks (Schnakenberg *et al.*, 2012). Female *Drosophila* directly regulate fertilization as she controls the release of sperm from her storage seminal receptacle. *C. elegans* are hermaphroditic and therefore make their own sperm, but they only make a finite amount during a short period of development which is then stored in the spermathecal. Chickens possess specialized sperm storage tubules in their oviduct where they can store sperm until needed for fertilization (Sasanami *et al.*, 2013). The mechanisms by which viable sperm can be stored for an extended period of time is of great interest in other species where sperm storage would be financially beneficial, such as pigs.

Conclusion

This article summarizes the conserved and distinct features and the underlying mechanisms of four important stages of oogenesis and ovulation. In oogenesis, a critical feature of meiosis is the presence of primary and secondary meiotic arrests. While the primary meiotic arrest is conserved across species and organisms, *C. elegans* lack the secondary meiotic arrest. Intriguingly, in *Drosophila* the secondary meiotic arrest occurs in metaphase of meiosis I while in other organisms it takes place at metaphase of meiosis II (Fig. 1). Another important point of consideration while comparing oogenesis and ovulation across species and organisms are the various intra-cellular regulators involved at different stages of oogenesis and the conserved and distinct signaling pathways/underlying mechanisms, as shown in Table 1. Careful consideration of these patterns of conservation are critical when selecting the ideal animal model with the most similarity to humans for that particular process.

Fig. 1 Conserved primary and secondary meiotic arrests during meiosis. “X” represents points of meiotic arrest. The primary meiotic arrest is conserved across all organisms in this article. *C. elegans* does not have a secondary meiotic arrest. *Drosophila* has a unique secondary meiotic arrest that occurs at metaphase of meiosis I (MI). All other animals considered have a secondary meiotic arrest at metaphase of meiosis II (MII). Modified from Von Stetina, J.R., Orr-Weaver, T.L., 2011. Developmental control of oocyte maturation and egg activation in metazoan models. Cold Spring Harb Perspect Biol 3, a005553.

Table 1 Summary of conserved processes and regulators of meiosis across species

	Primary meiotic arrest	Meiotic		Secondary meiotic arrest	Ovulation	
		Resumption	Maturation		Mono or poly	Store sperm
Human	Prophase I	LH	MPF	MII	Mono	No
Bovine					Mono	Yes
Chicken					Poly	No
Mouse						
Porcine						
<i>Xenopus</i>		Progesterone				
<i>Drosophila</i>		Unknown		MI	Mono	Yes
<i>C. elegans</i>		MSP		None

Introduction

More numerous than any other animal on Earth and found on every continent, insects are prolific and display diverse modes of reproduction (Thornhill and Alcock, 1983). A few reproduce asexually in true parthenogenetic fashion in which males are absent and unfertilized eggs develop into females. The vast majority reproduce sexually, with females either receiving sperm directly during copulation or indirectly collecting sperm packages males deposit in the environment. In some insects, fertilization determines whether the egg develops into males or females. In most Hymenopterans, eggs that are fertilized develop into females while unfertilized eggs develop into males. Female insects are capable of producing enormous numbers of progeny. Per day, a female fruitfly can lay 60 eggs, a honeybee queen 2000 eggs, and a termite queen 43,000 eggs (Klowden, 2013).

The process of producing and maturing an oocyte that is ready for to be fertilized and support embryonic development is composed of several sequential steps: oogenesis, ovulation, movement of the egg down the oviducts, fertilization (in the uterus), and finally deposition of the egg onto the food substratum. Each step is regulated and may feedback on steps preceding it in a regulatory feedback loop. *Drosophila melanogaster*, with its wealth of genetic and molecular tools, has served as a model organism for studying the various steps of this process (Bratu and McNeil, 2015; Hales et al., 2015). This article will focus on oogenesis, ovulation, and oviposition in *D. melanogaster* and highlight the insights provided by the myriad tools available in *Drosophila*.

Ovary Structure

Eggs are produced by the ovaries, which are composed of tubular units called ovarioles. The number of ovarioles per ovary varies from species to species and can be influenced by genotype and environmental conditions (Buning, 1994; Sarikaya et al., 2012). The number of ovarioles determines how many eggs the female is capable of producing. For example, *Drosophila* has 16–20 ovarioles/ovary, the honeybee queen 100–180 and the termite queen 1200. The ovarioles of the *Drosophila* ovary are held together by the peritoneal sheath (a vein-like network of muscle layer that surrounds each of the two ovaries) and converge basally where they attach to the lateral oviduct (King, 1970; Fig. 1). Ovariole development in *Drosophila* is dependent on formation of terminal filaments (TF) which are composed of stacks of 7–10 terminal filament cells (TFC) (Godt and Laski, 1995). Nutrition and rearing temperature during larval development influences the number of terminal filaments that develop and ultimately the number of ovarioles (Godt and Laski, 1995; Sahut-Barnola et al., 1995; Sarikaya et al., 2012). Larva that are provided with additional yeast in their food have more TFCs, TFs, and ovarioles while those on nutrient poor diets have fewer TFCs, TFs, and ovarioles. Rearing at temperatures below 21°C or above 25°C also results in ovaries with fewer ovarioles. At 18°C, the total number of TFCs is not affected but there are more TFCs per TF, thus fewer TF and fewer ovarioles.

Each ovariole is composed of three distinct regions: terminal filament at the anterior end; the germarium which houses the germline stem cells and differentiating germ cells, and produces the egg chambers; and the vitellarium which contains a series of consecutive developing egg chambers, each in a more advanced developmental stage than the one located anterior to it. There are two major types of ovarioles: panoistic in which maturation of the oocyte occurs without support of nurse cells; and meroistic in which the maturation is supported by associated nurse cells that synthesize and supplement the oocyte with organelles, RNA, and other macromolecules. Meroistic ovarioles can be further subclassified as telotrophic or polytrophic. In telotrophic-meroistic ovarioles (e.g., Hemiptera, Coleoptera), the nurse cells are restricted to the germarium but maintain a connection with the maturing oocyte by cytoplasmic processes called nutritive chords. In contrast, the nurse cells and oocyte in polytrophic-meroistic ovarioles stay connected and progress along the length of the ovariole as a unit (e.g., Hymenoptera, Trichoptera, Lepidoptera, and Diptera). The panoistic ovariole, characteristic of orders such as Odonata, Orthoptera and Dictyoptera, appears to be the ancestral type. Differences in ovariole structure do not limit the number of eggs a female can produce but can impact length of embryogenesis (Buning, 1994).

The *Drosophila* ovariole is polytrophic-meroistic. Each ovariole contains a series of consecutive developing egg chambers, each composed of a single oocyte and 15 nurse cells surrounded by a single layer of somatic cells called follicle cells. Consecutive egg chambers within the ovariole are connected by specialized interfollicular stalks (Fig. 1; King, 1970; Spradling, 1993; Deng and Bownes, 1998).

Oogenesis, *Drosophila* as a Model

Each oocyte develops within its own support unit, the egg chamber, which is formed in the germarium, a specialized structure at the anterior end of the ovariole (King, 1970; Spradling, 1993; Deng and Bownes, 1998; Matova and Cooley, 2001). The germarium is home to three different stem cell populations (germline stem cell, follicular stem cell, and escort stem cell) and the niche, a "regulatory microenvironment that controls stem cell self-renewal and differentiation" (Xie et al., 2008). The germline stem cell

Fig. 1 The *Drosophila* ovary – an example of Polytrrophic Meroistic Ovaries. Schematic drawing of the *Drosophila* ovary. The *Drosophila* female has a pair of ovaries (only one ovary is shown here), each of which consists of 16-20 ovarioles (top left), each of which contains several egg chambers at different developmental stages. One ovariole has been teased out and the boxed area is shown in more detail below. At the tip of each ovariole is the germarium (bottom left), which contains germline and somatic stem cells which divide continuously and give rise to new egg chambers. Somatic follicle cells are shown in blue; nurse cells, light blue; oocyte, dark gray; oocyte nucleus, white. Different consecutive egg chambers (stage II-XII) and the mature oocyte (stage 14) are shown at the bottom. Vitellogenesis (yolk uptake) starts at stage VIII. In the mature egg, the nurse cells and the follicle cells have degenerated, and the oocyte nucleus is arrested at metaphase I. orange: chorion – the egg shell. See text for further details. Figure modified from Silva, D., Jemc, J.C., 2015. Sorting out identities: an educational primer for use with "novel tools for genetic manipulation of follicle stem cells in the *Drosophila* ovary reveal an integrin-dependent transition from quiescence to proliferation". *Genetics* 201,13 -22. undergoes an asymmetric division, giving rise to a germline stem cell, which remains close to the terminal filament and cap cells of the germarium, and a cystoblast, which moves posteriorly. The cap cells maintain and support stem cell self-renewal. The cystoblast undergoes four rounds of synchronous mitotic divisions with incomplete cytokinesis, creating a cluster of 16 cells that remain connected by cytoplasmic bridges called ring canals. The cluster becomes enrobed by cellular extensions of escort cells which support their differentiation. The escort cells then hand off the cyst posteriorly where it becomes encapsulated by follicle cells which function in patterning the oocyte, physically shaping the egg chamber, synthesizing yolk proteins, secreting the egg shell, and creating specialized structures for sperm entry and respiration (Fig. 1).

Of the 16 cells in the egg chamber, one becomes the oocyte while the remaining 15 become nurse cells, which synthesize RNA, organelles, and macromolecules that supplement the developing oocyte, eventually dumping all of their cytoplasmic content into the oocyte (King, 1970; Spradling, 1993; Deng and Bownes, 1998; Matova and Cooley, 2001). The mitotic divisions that produce that 16-cell cyst are nonlinear and asymmetric resulting in 2 cells with 4 ring canals, and the remainder with 3, 2, or 1 ring canals. In addition to differences in the number of ring canals, the cells also differ in the amount of fusome, a cytoplasmic structure composed of vesicles and cytoskeletal components, inherited (Lin and Spradling, 1995). The fusome links all cells of the cyst together through the ring canals, synchronizing the cell cycle, and is required for specifying the future oocyte. The original fusome is inherited by the cystoblast from the germline stem cell. At each mitotic division, a new fusome forms in each ring canal, and one half of each new fusome fuses with the original fusome, resulting in one cell containing more fusome than its sisters. The cell with 4 ring canals and most fusomal material becomes the oocyte. A current model suggests that the fusome is an organizing matrix that directs oocyte determinants to a single cell. Once an oocyte is specified, the cystoblast becomes surrounded by follicle cells. The egg chamber then exits the germarium and enters the vitellarium where it completes development into a mature oocyte.

The follicle cells play an active role in the physical shaping and molecular patterning of the egg chamber and oocyte (Horne-Badovinac and Bilder, 2005). In the germarium, follicle cells envelope the 16-cell cyst, keeping each cyst separate. Polar cells, found at the anterior and posterior ends of the egg chamber, function in patterning follicle cells and the egg chamber; stalk cells connect consecutive egg chambers; and epithelial follicle cells envelope the entire egg chamber and undergo dramatic cell shape changes and movements that shape and pattern the egg chamber. In addition, the follicle cells secrete an extracellular matrix that encompasses the entire egg chamber and that may play a role in transforming the egg chamber from spherical to elliptical. As the egg chamber grows in size, the follicle cells proliferate, producing 1000 cells total.

Development of the egg chamber takes approximately 3 days and can be divided into 14 stages (Fig. 1). During this period, the egg chamber grows in volume 1000-fold, changing from a 20 μm sphere to an ovoid that is approximately 500 μm long and is

2.2–2.5 times longer than it is wide. Initially, the nurse cells and oocyte are approximately the same size (stages 1–6). As the egg chamber grows, the oocyte grows bigger than the nurse cells (stage 7–12), and ultimately occupies the whole egg chamber as the nurse cells shrink and undergo apoptosis (stage 13–14). In the early stages, mRNA and proteins made in the nurse cells are transported into the oocyte through the ring canals via the molecular motor dynein on microtubules and subsequently become localized in distinct regions within the oocyte. These mRNAs are essential for setting up the anterior-posterior and dorsal-ventral axes of the future embryo. Toward the end of this period, the egg chamber begins to grow more elongate along its anterior-posterior axis. Vitellogenesis begins at Stage 8 and the oocyte starts to uptake yolk proteins synthesized by the follicle cells and fat bodies, growing faster and becoming bigger than the nurse cells. During this period, the follicle cells undergo dramatic migrations and morphological changes. The majority of the follicle cells migrate toward the posterior end of the egg chamber where the oocyte is located while 50 remain over the nurse cells. At this time, there are 6–8 cells that do not participate in the migration. These are called border cells and they move in between the nurse cells and migrate toward the anterior end of the oocyte, coming to a rest across from the oocyte nucleus. The border cells create the pore in the micropyle, a specialized opening for sperm entry. In a third migration, follicle cells at the nurse cell-oocyte border, the so-called centripetal cells, move between the oocyte and nurse cells, covering the anterior end of the oocyte, and thus complete the encapsulation of the oocyte by follicle cells. The centripetal cells will form the operculum, a door through which the larva will exit the eggshell at hatching, and the cone structure that is the micropyle. The follicle cells covering the oocyte adopt a columnar shape while those of the nurse cells flatten (stretch cells). The columnar cells are secretory, and beginning at Stage 10A will secrete the components that make up the layers of the eggshell, the vitellum membrane and chorion, that protect the developing embryo from the environment. Beginning at Stage 10B, two patches of follicle cells located at the dorsoanterior of the oocyte are induced to create a pair of dorsal appendages, which are respiratory tubes for the embryo. During Stages 10B–14, the oocyte grows rapidly as the nurse cells transfer/dump their cytoplasm into the oocyte. By Stages 13 and 14, specialized eggshell structures (a pair of dorsal appendages, the micropyle, and the operculum) are visible, and the nurse cells and follicle cells undergo apoptosis (King, 1970; Spradling, 1993; Deng and Bownes, 1998; Matova and Cooley, 2001; Horne-Badovinac and Bilder, 2005).

The length of time to produce a mature egg from the germline stem cell stage depends on female genotype, age, and mating status, and environmental factors such as nutrition, degree of crowding, temperature, and humidity. Under optimal conditions, each ovariole is capable of producing on average two mature oocytes a day. The adult *D. melanogaster* female reaches her maximum daily output of egg production by day four and is able to maintain such a rate for two weeks.

The maturation of oocytes is regulated by several mechanisms (Drummond-Barbosa and Spradling, 2001; Soller *et al.*, 1999). Progression of oogenesis is negatively regulated by the presence of stage 14 oocytes in the ovary, which may exert mechanical pressure on the base of the ovary. In the ovaries of unmated females, two or three stage 14 oocytes are often present per ovariole, suggesting that oogenesis has ceased. After mating, the female ovulates the mature oocytes from the ovarioles and begins ovipositing, and maturation of additional oocytes commences. Thus, mating stimulates ovulation, which relieves the mechanical pressure on the ovary, which in turn stimulates oogenic progression via a feedback mechanism. It has been shown that the seminal fluid accessory gland proteins Acp70A (sex peptide) and Acp26Aa (ovulin) induces ovulation and stimulates oogenic progression. Sex peptide stimulates oogenic progression at a key control point of early vitellogenesis around stage 9. This control point regulates whether egg chambers will proceed with development or undergo apoptosis and is mediated by the balance of juvenile hormone and ecdysone (Soller *et al.*, 1999). In the sexually mature virgin female, when each ovariole contains 2 stage 14 oocytes, the production of new eggs is prevented by resorption of stage 9 oocytes. Oocyte resumption occurs because of high levels of 20-hydroxyecdysone (20E) in the hemolymph. Mating induces an increase in the level of juvenile hormone which relieves the 20E-mediated oocyte resorption. It has been shown that Acp70A (sex peptide) relieves this arrest, probably by increasing the level of juvenile hormone. Juvenile hormone stimulates progression of oocytes through the control point at stage 9, and it involves an increased uptake of yolk proteins from the hemolymph, as well as an increase of yolk protein synthesis in the ovary (Soller *et al.*, 1999).

Nutrient availability is another important regulator of oogenesis. Under starvation conditions, there is a decrease in proliferation of germline stem cells and follicle cells; cell death of cytotoblasts prior to encapsulation by follicle cells; accumulation of P bodies, cytoplasmic foci which act as a repository for mRNA storage or degradation, in previtellogenic egg chambers (Stage 6–8); and apoptosis of Stage 8 egg chambers (Drummond-Barbosa and Spradling, 2001; LaFever and Drummond-Barbosa, 2005; Burn *et al.*, 2015). Insulin signaling from the central nervous system and brain is required for mediating changes in proliferation rates and accumulation of P bodies in the response to changing nutrient levels, and these changes are reversible once high nutrient conditions are available again.

At the end of oogenesis, the mature oocyte is poised for fertilization and to begin embryogenesis. It contains maternal RNA, proteins and other molecules needed to initiate and support embryogenesis, and its nucleus is arrested at the first meiotic metaphase. The egg shell, composed of the chorion and vitelline membrane, is specialized to allow sperm binding and entry pre-fertilization and to protect the embryo during its development post-fertilization.

The Release of Oocytes From the Ovary – Ovulation

Ovulation, the release of an oocyte from the ovary, is a two-step process (Buning, 1994). First, the opening/rupturing of the oocyte follicle and of the innermost cells in the pedicel region at the base of the ovary releases the oocyte from the ovary. Then, contraction of the ovarioles, pedicels, and oviduct musculature moves the oocyte into the lateral oviduct. Ultrastructural studies of ovulation in the large aquatic beetle *Dysticus marginalis* (Coleoptera) and histological sections of whole ovaries in the mosquito *Culiseta inornata*

(Diptera) show that the pedicel is ruptured during ovulation and that the appearance of the first mature oocyte at the pedicel region triggers autolysis of the pedicel's innermost cells, opening the plug and releasing the mature oocyte from the ovariole (Buning, 1994, Fox and Brust, 1996).

For some insects, mating initiates ovulation (Grillot and Raabe, 1989; Raabe, 1986). In the blood-sucking hemipteran *Rhodnius prolixus*, for example, virgin females retain eggs in the ovary for many days while mated females deposit eggs soon after they are formed (Pratt and Davey, 1972). Ovulation in unmated *D. melanogaster* females, in contrast, occurs at a very low rate (1 egg/day) and becomes dramatically increased by mating (Heifetz *et al.*, 2000). Some insects, such as walking sticks, ovulate one oocyte at a time (*Clitumnus extradentatus*, Mesnier-Sabin, 1981; *Carausius morosus*, Thomas, 1979), while other insects, such as Orthoptera, ovulate oocytes from all ovarioles simultaneously. It is not known which mechanism operates in *D. melanogaster*.

Ovulation, *Drosophila* as a Model

Mature unmated *D. melanogaster* females spontaneously ovulate at a very low rate (~1 egg/day). Mating, however, dramatically and quickly increases the ovulation rate. Within 90 min post-mating, an increase in ovulation is evident and this increased rate is sustained for several days. A mated female can ovulate about 60 eggs a day for several days after mating. King (1970) indicated that degeneration of the innermost cells at the base of the ovariole, which plugs the entrance to the lateral oviduct, and massive muscle contractions at the base of the ovary and oviducts move the oocyte from the ovariole into and down the oviduct, to the uterus where fertilization takes place (Fig. 2). As occurs in mammals, the follicle cells remain in the ovary and form a "corpus luteum" which accumulate yellowish pigmentation and express genes encoding steroid hormone biosynthetic enzymes that are required for female fertility (Deady *et al.*, 2015).

In *Drosophila*, as in other insects that been studied thus far, rupturing of the follicle is a two-step process: 1) degradation of the posterior follicle cells of the mature oocyte and squeezing the remaining follicle cells toward the anterior, as the oocyte moves down into the lateral oviduct, and 2) rupturing of the follicle. Follicle rupturing, and oocyte release require the activity of proteolytic enzymes like matrix metalloproteinase 2 (Mmp2) which is expressed in the posterior follicle cells of stage-14 egg chambers. Reducing the expression level of *Mmp2*, specifically in stage 14 follicle cells, decreases ovulation and egg-laying rate. *Mmp2* activation is stimulated by octopamine. Octopamine binds to octopamine receptors in mushroom bodies (OAMB) located on mature follicle cells which leads to an increase in intracellular CA^{2+} that stimulates *Mmp2* activity. Furthermore, it was found that Shade, an enzyme involved in the last 4 stages of 20-hydroxyecdysone (20E) biosynthesis, is highly active in stage 14 follicle cells, converting ecdysone to the more active 20E. 20E signaling in stage 14 follicle cells is needed to stimulate *Mmp2* response to octopamine resulting in follicle rupture and ovulation (Lee *et al.*, 2003; Deady *et al.*, 2015; Knapp and Sun, 2017).

Octopamine signaling from the central nervous system coordinates an egg's release from the ovary and its passage into the oviduct. Octopamine binds G-protein coupled beta adrenergic-like octopamine receptors (*octβ2r*) and OAMB that are expressed in the oviduct epithelium. Octopamine binding stimulates a downstream cascade which may lead to relaxation of muscles and secretion of fluid for egg movement and possibly for egg activation. Octopamine might increase the amplitude of ovarian contraction and relax the oviduct musculature, allowing the oocyte to move into the oviduct more easily (Middleton *et al.*, 2006). Recently, Rubinstein and Wolfner (2013), showed that Ovulin relaxes the oviduct musculature, indirectly, by increasing the number of octopamine synaptic sites in the female reproductive tract after mating. In addition, Lim *et al.* (2014) found that *octβ2r* expressed in oviduct epithelial cells are essential for ovulation and movement of eggs along the reproductive tract. Homozygous *octβ2r* mutants are female sterile. Lim *et al.* (2014) suggests that mating activates octopamine neurons which innervate the oviduct. In addition, molecules released from secretory cells of *Drosophila* female reproductive glands, the spermathecal secretory cells and the female accessory glands (both connected by a thin stalk to the uterus), are required for efficient ovulation and egg movement along the female reproductive tract (Sun and Spradling, 2013; Schnakenberg *et al.*, 2011).

Activation of the egg to start development is triggered by fertilization in many animals (e.g., frogs, mice, other mammals), whereas in others, including *Drosophila*, activation is triggered by contact spawning media or squeezing of the egg and coming in contact with the oviduct environment. In *Drosophila*, ovulation initiates egg activation. Shortly after the onset of ovulation, while most of the egg is still in the ovary (Fig. 2), the egg starts to become impermeable to small molecules. The egg's impermeability increases progressively as the egg moves into the lateral oviduct. Once the egg is in the common oviduct, just shortly before the egg enters the uterus, cross-linking of the vitelline membrane proteins increases and meiosis resumes. Thus, ovulation causes changes in the egg that prepare it for fertilization in the uterus and subsequent embryogenesis. Another consequence of activation, resumption of translation, also initiates without fertilization in *Drosophila*.

Control of the Egg-Laying Process

Drosophila females begin to ovulate as early as 1.5 hrs after mating and by 6 hrs after mating has begun to deposit eggs at high rate. What regulates and sustains the high rate of egg-laying after the female is mated?

Neuro-hormonal regulation. The female reproductive tract is innervated by two pairs of nerves that branch separately from the abdominal median nerve trunk (AbNvTr) (Middleton *et al.*, 2006; Heifetz, 2004). One nerve projects to the junction of the ovaries and lateral oviduct, where it branches repeatedly. From here the nerves radiate anteriorly across the surface of the peritoneal sheath.

Fig. 2 Stages of ovulation in *Drosophila*. Schematic drawing of different stages of oocyte release from the ovary, based on Heifetz *et al.* (2001), which documented the positions of the eggs in the female oviduct at the time of dissection: (A) Eggs at positions I & II are mostly in the ovary and their posterior ends are at the anterior end of the lateral oviduct; (B) Eggs at position III are partly in the lateral oviduct and eggs at position IV have already reached the junction of the lateral and the common oviducts, but still remain partly in the ovary; (C) Eggs at position V are within the common oviduct and completely out of the ovary. As ovulation triggers egg activation, oocytes that have moved further in the lateral oviduct toward the common oviduct (i.e. stages III–V) are more likely to have been activated than those that are just at the anterior part of the lateral oviducts (i.e. stage I & II). Bottom right is a schematic drawing of the *Drosophila* female reproductive tract. The black box encloses the regions documented in (A)–(C). AG, accessory gland; CO, common oviduct; LO, lateral oviduct; OV, ovary; SP, spermatheca; SR, seminal receptacle; UT, uterus. Graphics by Zohar Nir-Amitin. Reproduced from Heifetz, Y., Yu, J., Wolfner, M.F., 2001. Ovulation triggers activation of *Drosophila* oocytes. *Dev. Biol.* 234, 416–424.

Studies of oviduct innervation in *Drosophila* reveal that the female oviduct is heavily innervated and receives input from aminergic, peptidergic (type II), and glutamatergic (type I) nerve terminals. Each of type of nerve terminal secretes specific neurohormones/neurotransmitters that elicits a specific response, such as muscle contraction or muscle relaxation. Aminergic nerves synthesize and release monoamines such as octopamine, serotonin, dopamine; peptidergic (type II) nerves synthesize and release peptides such dromyosuppression (DMS); and glutamatergic (type I) nerves synthesize and release glutamate which is the fast-excitatory neurotransmitter. In unmated females, octopamine, serotonin, and DMS immunoreactive nerve termini were found in all regions

of the reproductive tract and could serve neuromodulator functions in the female reproductive tract by regulating muscle contraction. Octopamine regulates ovulation rate in *Drosophila* and oviduct muscle contractions in locusts; serotonin regulates muscle contraction in locust oviducts; and DMS regulates contraction of *Drosophila* heart muscle and may regulate muscle contractions in the reproductive tract.

Octopamine, serotonin, and DMS often co-localized in the female reproductive tract, but each had a unique distribution throughout the tract. Furthermore, each region of the reproductive tract contains a unique, region specific combination of neuromodulators. These unique combinations of neuromodulators could potentially induce specific and different muscle modality (relaxation vs. contraction) in each specific region of the female reproductive tract (e.g., oviduct, uterus) that is needed to push the egg downward (Heifetz and Wolfner, 2004; Heifetz *et al.*, 2014).

Secretion. There are two major secretory glands in the female reproductive tract, the spermathecae, a sperm storage organ, and the female accessory glands. The spermatheca is surrounded by a layer of secretory glandular cells (spermathecal secretory cells) and a thick layer of fat body cells. Thus, two types of secretion, a glandular and a fat body-derived, may be produced by the spermathecae. When both the spermathecal secretory cells and female accessory glands were genetically ablated early in development, the female is completely sterile. Furthermore, reduction in the number of secretory cells in both glands during early development greatly decreased the ovulation rate. In addition, knocking down the nuclear hormone receptor - *hormone receptor-like in 39* (*hr39*) (required for normal development and function of the spermathecae and female accessory glands), in the secretory cells of both glands significantly increased the time that is required for ovulation. Mutations in *hr39* result in ovaries that are full of mature oocytes, but only few oocytes are released from the ovary (Sun and Spradling, 2013). Interestingly, genetic ablation of the spermathecal secretory cells later in development reduced female egg laying rate, mainly affecting the release of an egg from the uterus post fertilization. This completely changed the mode of reproduction to ovoviviparity, in which eggs remain in the uterus until they are ready to hatch (Schnakenberg *et al.*, 2011).

Mating components. Seminal fluid and sperm transferred to the female reproductive tract during mating have a central role in initiating and regulating the egg-laying process. Immediately after mating the reproductive tract supports the movement of sperm into the storage organs, but from 1.5 hrs after mating onwards the reproductive tract supports and regulates egg movement along the tract, in synchrony with moving sperm to the site of fertilization. Seminal fluid proteins and sperm are both required to stimulate oogenic progression and egg-laying. Seminal fluid proteins (e.g., ovulin) been also shown to initiate ovulation (Wolfner, 2009).

Different aspects of mating (sperm, seminal proteins, other seminal components, physical effects) also, independently, modulate changes in neuromodulator (octopamine, serotonin, octopamine, DMS) levels in the female reproductive tract. Interestingly, mating regulates the available combinations of neuromodulators in different regions of the *Drosophila* reproductive tract (i.e. induce or inhibit release of neuromodulators from the nerve termini). For example, at 90 min after the start of mating at ovulation onset, octopamine immunoreactivity decreases relative to unmated in the uterus. Serotonin, however, decreases in the ovary but increases in the common oviduct. DMS immunoreactivity decreases in the ovary and the common oviduct and increases in the uterus. This clearly indicates that mating changes region/time-specific balances among these neuromodulators, allowing the initiation of ovulation and movement of eggs (Heifetz *et al.*, 2014).

Conclusion

For many organisms, the female reproductive tract is a vital component in the process of internal fertilization. It facilitates the production and passage of gametes, gamete activation, and gamete fusion. Mechanisms that facilitate ovulation and egg-laying in many insects, including *Drosophila*, are still not fully understood. While insects display diverse modes of reproduction, the process of producing an egg has many parallels and show different degrees of conservation among insects, and beyond, highlighting many general principles of oogenesis, egg maturation and ovulation. Interestingly, recent studies on ovulation highlighted a degree of conservation between mammals and *Drosophila* in molecules that mediate the communication between the reproductive tract and gametes. More detailed studies about the cellular and molecular processes occurring in the female reproductive tract leading to oogenic progression, ovulation and egg activation in different insect from various reproductive modes is warranted. A comparative approach between insects and mammals could bring forth new insights into mammalian female reproduction and infertility, and in designing a new generation of pest control tools.

Glossary

Cdk1 A highly conserved protein that functions as a serine/threonine kinase and is a key player in cell cycle regulation.

cyclic AMP A second messenger for intracellular signal transduction.

cyclin B A member of the cyclin family that is necessary for the progression of cells into and out of M phase of the cell cycle.

Follicle-stimulating hormone A gonadotropin, a glycoprotein polypeptide hormone, that is synthesized and secreted by gonadotropic cells of the anterior pituitary gland, and which regulates the development, growth, pubertal maturation, and reproductive processes of the body.

G protein-coupled receptors A large protein family of seven-transmembrane domain receptors that detect a ligand outside the cell and activate internal signal transduction pathways.

G proteins A family of proteins that act as molecular switches inside cells, and that are involved in transmitting signals from a variety of stimuli outside a cell to its interior.

Germinal vesicle The nucleus of an oocyte that is arrested in prophase of meiosis I.

Germinal vesicle breakdown The dissolution of the nucleus of an oocyte that is arrested in prophase of meiosis I.

Gonad index The growing state of gonads calculated as gonad weight/body weight $\times 100$.

Gonadotropin-releasing hormone A peptide hormone responsible for the release of follicle-stimulating hormone and luteinizing hormone from the anterior pituitary.

Greatwall kinase Gwl is originally described as a nuclear protein required for proper chromosome condensation and M phase progression.

Insulin-super family A group of evolutionarily related proteins that are characterized by having three disulfide bonds in a characteristic motif.

Luteinizing hormone A hormone produced by gonadotropic cells in the anterior pituitary gland. In females, this hormone is a trigger for ovulation and the development of the corpus luteum. In males, luteinizing hormone acts on Leydig cell to produce testosterone.

Maturation-inducing hormone A hormone that acts on oocytes to reinitiate meiotic arrest.

Maturation-promoting factor The complex of cyclin B and cyclin-dependent kinase 1 (cdk1) to stimulate the mitotic and meiotic phases of the cell cycle.

1-Methyladenine The maturation-inducing hormone of starfish.

Ovarian follicle cells Cells surrounding an oocyte in a single layer.

Relaxin A peptide hormone belonging to the insulin/insulin-like growth factor/relaxin superfamily that controls pregnancy and facilitates parturition in placental animals.

Relaxin-like gonad-stimulating peptide A hormone that acts on the gonads to induce gamete shedding by way of the production of maturation-inducing hormone in starfish.

Nomenclature

cAMP Cyclic AMP or 3',5'-cyclic adenosine monophosphate

cdk1 Cyclin-dependent kinase 1

FEED Follicular envelop breakdown

FSH Follicle-stimulating hormone

GI Gonad index

GnRH Gonadotropin-releasing hormone

GPCR G protein-coupled receptor

G proteins Guanine nucleotide-binding proteins

GSS Gonad-stimulating substance

Gwl Greatwall kinase

LH Luteinizing hormone

1-MeAde 1-Methyladenine

MPF Maturation (M phase)-promoting factor

RGP Relaxin-like gonad-stimulating peptide

Introduction

Echinoderms, which are exclusively marine animals, are divided into five classes, the Asteroidea (starfishes), Ophiuroidea (serpent-stars), Echinoidea (sea-urchins, heart-urchins, and sand-dollars), Holothuroidea (sea-cucumbers), and Crinoidea (sea-lilies and feather-stars). The male and female gametes, fertilized eggs, and embryos of echinoids have been one of the major materials for analyses of the mechanisms of gametes and in handling them in laboratories. Especially in sea urchins, both eggs and spermatozoa are readily used in fertilization experiments and can be obtained easily by injecting isotonic potassium chloride into the body cavity or by providing brief electrical stimulation. This is because sea urchin oocytes have already accomplished meiotic maturation within the ovary during the breeding season long before spawning occurs. However, because of the completion of meiosis within the ovary, sea urchin eggs are not suitable for analytical investigations on the mechanism of oocyte maturation. In contrast, in starfish, meiosis is arrested at the prophase of the first maturation division in fully grown oocytes just before spawning, and a ripe ovary contains a large number of such oocytes of almost equal size. Furthermore, in the starfish *Patiria pectinifera*, the time required for spawning and breakdown of germinal vesicles under the influence of some active substances is relatively short, less than 30 min, and the process can be observed using a microscope when oocytes are isolated in seawater. Thus, starfish is a suitable material for elucidating the mechanisms of oocyte maturation and spawning (ovulation). This article reviews the endocrine regulation of oocyte maturation and ovulation in starfish. Oocyte growth is also briefly described.

Oogenesis

Annual reproductive cycles are defined in echinoderms by estimation of breeding seasons from observations of spawning, histological examination of the ovaries, and calculation of the gonad index (GI) (gonad weight/body weight $\times 100$). The starfish *Patiria pectinifera* is commonly found in shallow waters of the Pacific and Japan Sea. The breeding season of this species varies greatly depending upon geographical locality, and occurs relatively earlier in southern Japan and later in northern Japan.

The growth of oocytes in starfish *Patiria pectinifera* is divided into five stages on the basis of their cytological appearance (diameter of oocytes) (Kanatani, 1979, 1985) (Fig. 1(A)). The primary oocytes at stage I are about 10 μm in diameter, with nuclei containing conspicuous strands of chromatin. These oocytes are still present in the gonial cysts and are not surrounded by follicle cells. Numerous synaptonemal complexes are seen throughout the nucleus. The oocytes at stage II (10–30 μm in diameter) are surrounded by a single layer of follicle cells. Some cortical granules first appear in the cytoplasm near the nucleus. In late stage II, some yolk granules begin to appear, often arranging themselves in groups. A marked increase in oocyte size begins with stage III (30–70 μm in diameter). The cytoplasm acquires an organization characteristic of a cell actively engaged in the synthesis and export of proteins. Lampbrush chromosomes are occasionally seen in some nuclei. There is a massive increase in the size of oocytes (70–150 μm in diameter) at stage IV, due in part to a further accumulation of yolk granules. Beginning at stage V, the vitelline envelope appears in the extracellular space between follicle cells and oocytes. The cortical granules in oocytes at this stage are present just beneath the oocyte surface. The oocyte changes little in size (up to ~ 160 μm in diameter) from the end of stage IV.

Fig. 1 (A) Meiotic stages in starfish oogenesis and maturation. The growth of oocytes of *Patiria pectinifera* is divided into five stages on the basis of their cytological appearance (diameter of the oocyte) as follows: stage I (ca. 10 μm), stage II (10–30 μm), stage III (30–70 μm), stage IV (70–150 μm), and stage V (>150 μm). (B) Immature oocyte of the starfish *Patiria pectinifera*. The oocyte possesses germinal vesicle, and is tightly surrounded by an envelope consisting of follicle cells. (C) Mature oocyte after 30 min of 1-MeAde treatment. The germinal vesicle and follicular envelope are breakdown. (D) Mature oocyte after 60 min of 1-MeAde treatment. The first polar body is discharged. (E) Fertilized egg. After insemination, fertilization membrane is formed. Bars show 100 μm .

Some vertebrate hormonal steroids, such as 17β -estradiol and progesterone, are present in starfish ovaries (Kanatani, 1985). These steroid hormones probably stimulate oocyte growth by activating vitellogenesis in Echinoderms.

Oocyte Maturation

The period of oocyte growth is followed by a process called oocyte maturation (the resumption of meiosis), which occurs prior to ovulation and is a prerequisite for successful fertilization. Gonadotropins play important regulatory roles in reproduction in vertebrates and invertebrates. In vertebrates, hypothalamic gonadotropin-releasing hormone (GnRH) acts on the pituitary gland to stimulate the release of follicle-stimulating hormone (FSH) and luteinizing hormone (LH), which then act synergistically to promote gamete maturation and gonadal function (Pierce and Parsons, 1981).

In starfish, a ripe ovary contains a large number of fully grown oocytes of almost equal size. Each oocyte possesses a large nucleus (a germinal vesicle), which remains arrested in late prophase of the first maturation division, and is surrounded by a single layer of follicle cells, which adhere firmly to each other and to the ovarian wall (Fig. 1(B)). These immature oocytes cannot be fertilized, and they still require maturation and ovulation processes that are induced by hormonal substances (Fig. 2(A)). Fertilization eventually occurs after these oocytes are spawned into the seawater (Fig. 1(E)), outside of the female's body, for most starfish.

Relaxin-Like Gonad-Stimulating Peptide

The first report of a gonadotropic substance in an invertebrate was the observation that extracts of radial nerve cords from the starfish *Asterias forbesi* induce shedding of gametes when injected in this species (Chaet and McConnaughy, 1959). The active substance was named gonad-stimulating substance (GSS) and was characterized biochemically as a peptide hormone (Kanatani, 1979). In 2009, GSS was purified from the radial nerve cords of starfish *Patiria pectinifera* (Mita et al., 2009). The purified hormone is a heterodimeric peptide with a molecular weight of 4740, comprising an A-chain of 24 amino acids and a B-chain of 19 amino acids, with disulfide cross-linkages (Fig. 2(B)). Furthermore, the A-chain contains a cysteine motif CCxxxCxxxxxxxxC, which is a signature sequence of the insulin/insulin-like growth factor/relaxin superfamily. More specifically, phylogenetic sequence analysis revealed that starfish GSS is a member of the relaxin-type peptide family (Mita et al., 2009; Mita, 2016). Therefore, the GSS identified in *Patiria pectinifera* has been designated as relaxin-like gonad-stimulating peptide or RGP.

Subsequently, orthologs of *Patiria pectinifera* RGP were identified in other starfish species (Mita, 2016). At least three kinds of RGP molecules are found in the class Asteroidea. The chemical structure of *Patiria pectinifera* RGP is mostly conserved among starfish of the order Valvatida beyond species including *Patiria miniata*, *Certanardoa semiregularis* and *Acanthaster planci*. In contrast, the chemical structures of RGP identified in *Asterias amurensis* and *Aphelasterias japonica* of the order Forcipulatida are quite different from that of *Patiria pectinifera* RGP. The amino acid identity levels between *Asterias amurensis* RGP and *Aphelasterias japonica* RGP were 84% for the A-chain and 90% for the B-chain. In contrast, the amino acid sequences of *Asterias amurensis* RGP and *Aphelasterias japonica* RGP were not quite as similar as that of *Patiria pectinifera* RGP, with homology levels of 58% and 58% for the A-chain, 73% and 68% for the B-chain, respectively.

Cross-experiments among different starfish revealed that RGP generally acts non-species-specifically, with some exceptions. Because the chemical structure of *Patiria pectinifera* RGP is almost the same as those of species among the order Valvatida, *Patiria pectinifera* RGP can induce oocyte maturation and ovulation in ovarian fragments from *Patiria miniata*, *Certanardoa semiregularis* and *Acanthaster planci*. Furthermore, *Patiria pectinifera* RGP was active in *Asterias amurensis* and *Aphelasterias japonica* ovaries. In contrast, neither *Asterias amurensis* RGP nor *Aphelasterias japonica* RGP induced spawning in the ovarian fragments of *Patiria pectinifera*, although *Asterias amurensis* RGP was active in *Aphelasterias japonica* ovaries. It may also be possible that, because of low specificity of the receptor proteins in ovarian follicle cells of *Asterias amurensis* and *Aphelasterias japonica*, *Patiria pectinifera* RGP can affect the ovaries of *Asterias amurensis* and *Aphelasterias japonica*.

Fig. 2 (A) Hormonal mechanism of starfish oocyte maturation. (B) Starfish gonadotropin, relaxin-like gonad-stimulating peptide (RGP), identified from radial nerve cords of *Patiria pectinifera*. (C) Starfish maturation-inducing hormone, 1-methyladenine (1-MeAde).

Enzyme-linked immunosorbent assays using a specific antibody against *Patiria pectinifera* RGP revealed that high activity of RGP was present in the radial nerve cords and circumoral nerve rings, but RGP was undetectable in the gonads. RGP was localized predominantly in the neurosecretory granules on the supporting cell layer just beneath the outer cuticle of the radial nerve cords. On the basis of *in situ* hybridization, the mRNA of RGP was detected in the peripheral area of radial nerve cords proximal to the tube-feet, but not at the side of the haemal sinus. Positive immunoreactivities with the RGP antibody were also located in the cuticle layer of the outer surface of the radial nerve cords of *Patiria pectinifera* (Mita, 2016). Furthermore, RGP transcripts were abundantly expressed by cells in the arm tips of the starfish *Asterias rubens*. Thus, RGP is *de novo* synthesized in the cells as a prepro-RGP translated from its mRNA at first. After the formation of three disulfide cross-linkages between the A- and B-chains and within the A-chain, mature RGP is produced by elimination of the signal and C-peptides.

RGP was detected in the coelomic fluid only when starfishes were undergoing natural spawning (Kanatani, 1979, 1985). RGP was never found in the coelomic fluid in individuals that were not undergoing spawning. This is evidence that RGP is a hormone. On the other hand, RGP content in the radial nerve cords remains constant throughout the year, regardless of breeding and non-breeding season. In an *in vitro* experiment, RGP was capable of being released from the radial nerve cords in the presence of ionomycin. Perhaps, an increase in the level of intracellular Ca^{2+} is closely associated with RGP secretion. RGP seems to be transported from the ectoneural epithelium of the radial nerve cords to the radial haemal sinus. This sinus is connected to axial, visceral, and genital haemal sinuses of the haemal system. Presumably, RGP is transported from radial nerve cords to the gonads through the haemal system. It is also assumed that RGP, being secreted from the radial nerve cords, acts on ovarian follicle cells *via* coelomic fluid. At present, the secretion mechanism and transport pathway of RGP has not been elucidated.

Other than starfish RGP, a pentapeptide (NGIWamide), cubifrin, induces oocyte maturation and spawning behavior in the sea cucumber *Apostichopus japonicus* in a very similar manner to RGP of starfish (Kato *et al.*, 2009). However, cubifrin can induce maturation in follicle-enclosed oocytes only in the presence of the ovarian wall. Thus, the action of cubifrin resembles GnRH rather than gonadotropin.

Maturation-Inducing Hormone

Spawning behavior and subsequent spawning are observed in the females of *Patiria pectinifera* with fully grown ovaries upon injection of RGP into the body cavity. The starfish starts moving upward along the walls of the aquarium and then sheds its gametes within 30 min (Mita *et al.*, 2009). Although RGP is the primary mediator of oocyte maturation and spawning in starfish, its effect is indirect (Fig. 2(A)). Resumption of meiosis in immature oocytes and spawning from the ovary is induced by a second mediator, maturation-inducing hormone, identified as 1-methyladenine (1-MeAde) in starfish (Kanatani *et al.*, 1969; Kanatani, 1979, 1985) (Fig. 2(C)). RGP controls 1-MeAde production in ovarian follicle cells.

RGP bound specifically to a membrane preparation of ovarian follicles of *Patiria pectinifera*, and isolated follicle cells cultured with RGP showed a dose-related increase in cyclic AMP (cAMP) production, coinciding with an increase in 1-MeAde production. Thus, the action of RGP is mediated through the activation of its receptor, G-protein, and adenylyl cyclase in follicle cells. However, RGP failed to induce 1-MeAde and cAMP production in follicle cells of *Patiria pectinifera* ovaries during oogenesis (Mita, 2016). At the maturation stage, follicle cells acquire the potential to respond to RGP by producing 1-MeAde and cAMP. Adenylyl cyclase activity in follicle cells of fully grown ovaries is stimulated by RGP in the presence of GTP. Of note, the mRNA for the α subunit of the Gs-protein (*G α s*) was not detected in follicle cells of oogenesis-stage ovaries. The expression level of *G α s* in follicle cells also increased significantly as the size of the oocytes increased. This revealed that the potential of follicle cells to respond to RGP by producing 1-MeAde and cAMP occurs by *de novo* synthesis of the *G α s* protein.

Furthermore, 1-MeAde produced under the influence of RGP is newly synthesized, rather than being previously stored within ovarian follicle cells or a breakdown product of some 1-MeAde-containing substance, such as ribonucleic acid (Kanatani, 1985). The RGP-dependent 1-MeAde production also involves a methylation process. Because RGP causes a reduction in the intracellular level of ATP after 1-MeAde production, 1-MeAde is synthesized from ATP *via* the methylation process from S-adenosylmethionine in ovarian follicle cells of *Patiria pectinifera*.

Maturation (M-Phase)-Promoting Factor

In primary oocytes within ovaries, the cell cycle arrests generally at the prophase of the first meiosis. The release from prophase arrest in immature oocytes of *Patiria pectinifera* is induced by 1-MeAde, with no requirement for new protein synthesis (Kishimoto, 2015). On the other hand, the injection of 1-MeAde into fully grown starfish oocytes failed to induce maturation (Kanatani and Hiramoto, 1970). This revealed that 1-MeAde acts on the external oocyte surface, and that some hormonal message seems to be conveyed to the cytoplasm. Evidence for the activation of a third mediator, maturation-promoting factor (MPF), in the oocyte cytoplasm is that the cytoplasm from an oocyte of *Patiria pectinifera*, maturing after treatment with 1-MeAde, induces maturation when injected into an immature oocyte (Kishimoto and Kanatani, 1976). Starfish MPF, like that of *Xenopus* and fish, consist of two components: cyclin B and cyclin-dependent kinase 1 (Cdk1). MPF not only induces starfish oocyte maturation (Fig. 2(A)) but also regulates the G2/M-phase transition of mitosis from yeast to mammalian cells (Kishimoto, 2015).

Actually, 1-MeAde binds to an oocyte membrane receptor (Yoshikuni *et al.*, 1988). From the structure function relationship studied so far using many analogues of 1-MeAde, a lipophilic substitution on N1, an amino group at position 6, and a cationic charge are known to be pre-requisites for maturation-inducing activity (Kanatani, 1985). Any substitution in positions 7 or 9 or

a bulky 8-substituent is detrimental to the interaction between the hormone and its receptor. It was notable that the degree of biological activity for the induction of oocyte maturation decreases as the side chain at the N1-site is elongated, 1-MeAde > 1-ethyladenine > 1-propyladenine. This revealed that the molecular size at the N1-site is important for interaction with the receptor.

The receptor of 1-MeAde couples to the $\alpha\beta\gamma$ trimeric G protein (Chiba, 2000). After binding of 1-MeAde to its receptor, $G\beta\gamma$ subunits dissociate from the GTP-bound $G\alpha$ subunit, and the dissociated $G\beta\gamma$ stimulates phosphoinositide 3-kinase (PI3K), which brings about the activation of MPF (Chiba, 2000).

MPF is a universal regulator of M-phase in the eukaryotic cell cycle (Kishimoto, 2015). Its activation induces entry into M-phase and its subsequent inactivation is necessary for exit from M-phase. MPF consistently equates with the kinase cyclin B-Cdk1. 1-MeAde exerts its effects through the receptor, G-protein and PI3K. Subsequently, downstream of PI3K, the Akt switches the balance between the Wee1 family kinase, Myt1, and Cdc25 and causes the initial activation of cyclin B-Cdk1 at the meiotic G2/M-phase transition. In some condition, however, MPF is undetectable even though cyclin B-Cdk1 is fully active (Kishimoto, 2015). MPF was originally defined as a transferable activity that can induce the G2/M phase transition in recipient cells. According to classical microinjection assay results, MPF consists not only of cyclin B-Cdk1 but also Greatwall (Gwl) (Kishimoto, 2015). Involvement of Gwl in MPF can be explained by its contribution to the autoregulatory activation of cyclin B-Cdk1 and by its stabilization of phosphorylations on cyclin B-Cdk1 substrates, both of which are essential when MPF induces the G2/M phase transition in recipient cells.

Ovulation

Unlike sea urchins, neither electric stimulation nor contraction-inducing agents, such as potassium chloride and acetylcholine, induce spawning from intact starfish ovaries (Kanatani, 1979). In starfish, each immature oocyte within ovaries is tightly surrounded by an envelope consisting of follicle cells (Fig. 1(B)). Ovarian follicle cells are connected to the oocyte by slender cytoplasmic processes extending to the oocyte surface. These processes arise from the follicle cell cytoplasm, pass through the jelly coat and vitelline coat, and form characteristic desmosome-like junctions at their tips with the oocyte plasma membrane (Kishimoto *et al.*, 1984). After treatment with 1-MeAde, the follicular envelope of an isolated oocyte ruptures and forms a clump upon commencement of germinal vesicle breakdown by the oocyte (Fig. 1(C)). From this, the mature oocytes can move freely before their release from the ovaries (Kanatani, 1979, 1985; Kishimoto *et al.*, 1984). However, 1-MeAde does not induce contraction of ovarian wall. It is considered that acetylcholine secreted from the gonadal nerve cells after follicular envelop breakdown increases tension in the ovarian wall and leads to shedding of mature oocytes.

Therefore, starfish oocyte maturation and spawning (ovulation) induced by RGP can be understood as follows: RGP acts on ovarian follicle cells to produce 1-MeAde. 1-MeAde stimulates oocytes to activate intracellular MPF, which is a direct trigger for maturation and dissociation of the follicular envelope. After follicular envelop breakdown, the denuded mature oocytes become free within the ovary. Finally, acetylcholine-mediated contraction of the ovarian wall leads to spawning of the loose, mature oocytes.

MATERNAL RESERVES

Maternal RNAs, Fish & Amphibians

Caroline TY Cheung, Julien Bobe, and Violette Thermes, INRA, LPGP UR1037, Rennes, France

In fish, maternal RNAs that are incorporated into the developing oocytes include ribosomal RNA (rRNA), transfer (tRNA), and messenger RNA (mRNA), the two former of which are components of the protein translation machinery and the latter of which is used as a blueprint to synthesize proteins, as well as microRNA (miRNA) and other non-coding RNA (ncRNA), which are not used to make proteins, but instead play regulatory roles (Pauli *et al.*, 2011; Pelegri, 2003). These factors are produced by the mother based on her genome and deposited into the developing egg at a very early stage of oogenesis. This article will focus on the localization, regulation, and function of coding and non-coding RNAs.

Much of the knowledge we have on maternal RNAs in fish have been obtained from teleost species (ray-finned fishes that make up 96% of all fishes) including zebrafish (*Danio rerio*), medaka (*Oryzias latipes*), and to a lesser extent goldfish (*Carassius auratus*). These are all small aquarium fishes used as experimental laboratory models due to their ease of reproduction in captivity and abundant egg production that are easily handled in culture. Findings were also obtained from wild and farmed fish species, such as rainbow trout, salmon, and tilapia just to name a few. The major differences between fish species and other vertebrates are that their eggs are fertilized and develop externally and can be produced year-round. In this article, we will introduce the localization, regulatory mechanisms and function of some protein-coding and non-coding transcripts that have previously been investigated in fish eggs.

Localization of Maternally-Inherited mRNAs in the Oocyte

Fish eggs immediately upon fertilization are spherical in shape with various components, including maternal mRNAs, numerous organelles, yolk inclusions, proteins, as well as lipid droplets and pigments intermingled in the egg cytoplasm (Lubzens *et al.*, 2010). Subsequently, a distinct blastodisc embodied as a thin region of yolk-free cell cytoplasm (animal pole) is separated from the yolk, which takes up most of the egg (vegetal pole). Only the cytoplasm of the blastodisc, but not the yolk, undergoes subsequent cleavages or cell divisions to become the full embryo which generates a mound of cells that sits on top of the yolk (Fig. 1(E)). The chorion membrane, consisting predominately of the glycoproteins *zona pellucida* (*zp*) 2 and *zp*3, surrounds the embryo and expands upon fertilization with an enlarged fluid-filled perivitellin space in-between.

At the earliest stage of oogenesis in zebrafish, most of the maternal mRNAs that have been investigated are observed throughout the cytoplasm of the immature oocyte. However, some transcripts in the developing oocyte appear to be quite mobile and change localization during the course of oogenesis. During oogenesis, the animal/vegetal polarity of the egg is established by the functions of genes including *bucky ball*, which regulate the distinct distribution of maternal RNAs and the asymmetrical location of the germinal vesicle (oocyte nucleus) and micropyle (a specialized structure for sperm entry) (Marlow and Mullins, 2008). In the unfertilized mature egg, while certain maternal transcripts remain ubiquitously distributed throughout the cytoplasm, other mRNAs follow specific distribution patterns, including localization to the animal pole, vegetal pole, and cortex (Fig. 1) (Howley and Ho, 2000). β -catenin is an example of an mRNA that is dispersed evenly throughout the cytoplasm of the oocyte during the entire oogenesis and remains spread out in mature and fertilized eggs. Others including *zorba*, *pou2*, and *cyclin B* are found specifically at the animal pole, possibly with roles in specification of this axis, while genes that are related to the future dorsal/ventral axis formation (*swirl*, *wnt8a*, and *grip2*) and germ-line specificity (*dazl* and *brul*) are found in the vegetal pole. In addition, *vasa* is observed to have a uniform cortical localization along the animal/vegetal axis in mature zebrafish eggs.

Upon fertilization, almost all of the maternal transcripts are pulled into the blastodisc through cytoplasmic streaming or ooplasmic segregation, a process based on cytoskeletal actin filaments and microtubules that ensures the orderly partition of the maternal factors to the animal pole and the yolk components to the vegetal pole, with the exception of *dazl* which remains at the vegetal pole until the 4-cell stage. The transport of maternal RNAs, especially those that are relevant for dorsal/ventral axis formation, is further dependent on the "cortical rotation" mechanism, whereby a vegetal pole-based microtubule system is used to pull RNAs from the vegetal pole to the animal pole, as well as a more general animal pole-oriented transport system that involves the mediolateral cortex. Notably, the same maternal RNAs (*bucky ball* and *kif5Ba*) that are involved in this process are also responsible for the regulation and establishment of the germ plasm, which forms at the distal ends of the cleavage furrows of 4-cell embryos. This important structure contains maternal mRNAs that are necessary for germ-line specificity, such as *vasa*, *nanos1*, *brul*, and *dazl*, which is finally released from the vegetal pole (Kosaka *et al.*, 2007).

Fig. 1 Different distribution patterns of maternal transcripts in the mature fish egg. Maternally-accumulated mRNAs are localized to either the animal pole, evenly throughout the oocyte, cortically, or to the vegetal pole (A–D). However, there are some transcripts that are redistributed and change localization during oogenesis. (E) After fertilization, most of the transcripts are pulled into the animal cell cap by cytoplasmic streaming or cortical rotation.

Regulatory Mechanisms of Maternally-Inherited mRNA

RNAs are synthesized in the developing oocytes based on the maternal genome during oogenesis. The different RNA species that are stored in the egg are extremely important to the development of the embryos since they coordinate (1) early development, including cell division prior to the mid-blastula transition (MBT), (2) the expression of genes from the embryo's own genome, and (3) proper embryogenesis after MBT. The expression levels of transcripts differ depending on their function and maternal RNA levels decrease over time eventually being completely replaced by the embryonic RNAs, which are first expressed at MBT when zygotic genome activation (ZGA) occurs (Fig. 2). In fish, ZGA occurs at approximately the 1000-cell stage, in contrast to mammals where it begins earlier during the late 1-cell and early 2-cell stages. Most mRNAs such as *cytochrome P450 aromatase*, *zona pellucida*, and β -catenin are synthesized abundantly very early during oogenesis (stage I) and progressively decrease with still substantial amounts at fertilization, which are maintained until MBT (Howley and Ho, 2000). The quantity of some transcripts such as *star* and *apolipoprotein CI* are relatively small in very early oocytes (stage I), but they are progressively synthesized and accumulated during oogenesis peaking in later stage eggs and maintained until after fertilization. The amount of other mRNAs such as *bucky ball* is relatively constant throughout oogenesis and may increase in mature eggs until after fertilization.

After fertilization, translation of the maternal transcripts is under strict control to determine precisely their spatiotemporal synthesis, and the expression level of maternal RNAs is regulated by their stability and degradation since transcription does not occur before MBT. Many of the mRNAs are masked or repressed by binding to ribonucleoprotein particles, which inhibit the interaction of the transcripts with the translation machinery, until they are ready to be used. One clear example is the repression of transcripts for cell cycle regulatory proteins such as cyclins, which are activated in a very precise and timely manner to ensure proper cell division after fertilization. Another important mechanism for translational control of maternal transcripts is cytoplasmic polyadenylation driven by CPEB/zorba proteins, which bind to sequences in the 3'-untranslated regions of regulated mRNAs and mediate their storage, repression or translation. Notably, CPEB proteins are required for the activation of polyadenylation, which lengthen the poly(A) tail of transcripts, and subsequent translation of the stored maternal mRNA in the fertilized embryo. De-adenylation and shortening of the poly(A) tails, which lead to decapping of the 5' cap structure of transcripts, decrease their stability and subject them to degradation.

Fig. 2 Maternal and embryonic gene expression levels over time from fertilization to late embryogenesis. The total level of maternal RNAs starts to drastically decrease at the mid-blastula transition (MBT), at which point the “zygotic genome activation” occurs, and the level of embryonic gene expression begins to increase. There are two major waves of embryonic gene expression. Below the graph are images showing the medaka (*Oryzias latipes*) egg at various stages of embryogenesis: fertilization, 1-cell, 2-cell, 1000-cell, and 30–35-somite stages. Scale bar: 200 μ m.

Two major mechanisms have been described for the clearance and degradation of maternal RNAs in the developing embryo: one that is programmed and controlled by maternal factors and the other that is activated by embryonic factors (Mishima and Tomari, 2016). Both mechanisms depend on the shortened length of the poly(A) tail of the transcript based on the deadenylation status driven by the pan2-pan3 and ccr4-not deadenylase complexes. This leads to activation of decapping machineries involving the dcp1/2 complex which removes the 5' cap structure of transcripts and commits them to degradation by the xrn1 exonuclease. In addition, epigenetic changes such as methylation has been shown to mediate degradation; over one-third of zebrafish maternal mRNAs can undergo methylation at adenosines.

In general, *cis* elements in the transcripts in combination with sequence-specific RNA-binding factors that recruit degradation machineries are considered to contribute to both maternal- and embryonic-driven transcript decay. In contrast, a maternal factor that has been proposed to mediate maternal RNA decay involves codon identity or usage. Basically, there are uncommon synonymous codons within the open-reading frame of the maternal transcript that promotes its own degradation via the ccr4-not complex, which means that codon usage and amino acid composition influences RNA stability. The effect of codon usage also depends on the length of the 3'-untranslated region. Thus, the transcript not only conveys the genetic code which specifies the amino acid sequence, but also contains a conserved “codon optimality code” that shapes transcript stability and degradation (Bazzini *et al.*, 2016).

The most well-known embryonic factor that mediates maternal RNA clearance is the miR-430. The miR-430 is transcribed at the onset of the ZGA by maternally-accumulated transcription factors Nanog, Pou5f1 and SoxB1, and matured by the maternally-provided Dicer protein. Expression of miR-430 at the MBT significantly contributes to the clearance of many maternal mRNAs accumulated in the egg. The key role of this miRNA was first discovered by means of mutant embryos lacking maternal and embryonic Dicer activity (MZDicer^{-/-}) (Schier and Giraldez, 2006). In these mutants, synthesis of all embryonic miRNAs in the early embryo was impaired and gastrulation was drastically affected. Further, when the fertilized eggs were supplemented with exogenous miR-430, embryonic development could be partially restored. MiR-430 indeed promotes the deadenylation and decay of several hundreds of maternally-expressed mRNAs, and thus, contributes to the correct patterning of genes in the later embryo. These experiments clearly demonstrated the importance of early embryonic miRNAs, more specifically the miR-430, in the clearance of maternal mRNAs at the ZGA. However, it is believed that other miRNAs might also be involved in the mRNA turnover, but their identity still remains to be discovered.

Both the presence and absence of maternally-provided RNAs are important for proper embryogenesis; first, to coordinate early development of the embryo as well as promotion of ZGA, and then, their degradation is necessary for the progression of numerous subsequent processes, since it was shown that some maternal RNAs actually inhibit certain reactions after MBT. In the next section, we will introduce the functions of the maternally-inherited RNAs.

Function of Maternal mRNAs During Development

Despite the plethora of maternal transcripts (between 10,000 to over 30,000 in zebrafish) found in the fertilized egg, the number of and knowledge on maternal-effect genes, defined as those whose products, including mRNA, proteins, and other biomolecules, are

found predominately in the fertilized egg and are essential for the normal early development of the embryo before expression from the embryonic genome, remain low. Genetic manipulations to create mutants using model fish species have greatly expanded our understanding of maternal-effect genes. With this approach, it was observed that mothers with mutations in maternal-effect genes are phenotypically normal and viable, however, they suffer from subfertility or sterility due to the diminished quality of their eggs. The lack of or decreased expression of maternal-effect genes can result in decreased fertilization, as well as increased embryonic mortality and malformations.

Certain maternal transcripts that are present in the fertilized egg are essential for egg activation and the process of fertilization. Genetic screens showed that the maternal transcripts for *jump start*, *p11cv*, *clauastro*, *emulsion*, and *dp14nb* are critical for regulating changes in egg shape, ooplasmic segregation to the blastodisc, and chorion expansion, all of which are processes that occur during egg activation upon fertilization (Dösch *et al.*, 2004). Further, the *fue* mRNA is necessary for the congression of the sperm and oocyte pronuclei as well as chromosomal segregation during the subsequent cell divisions, thus, the lack of this transcript results in the failure to produce a proper diploid nucleus in the first cell of the embryo and subsequent cell divisions result in anucleate cells with local DNA accumulation in just one or two cells.

Many maternal RNAs have been found to be essential to the first cell cleavages or divisions following fertilization. It was found that lack of maternally-provided *aurora-A*, *cellular island/aurora-B*, *cellular atoll*, *acytokinesis*, *atomos*, *aura*, *barrette*, *cobblestone*, *indivisible*, *irreducible*, *nebel*, *weeble*, *bo peep*, *golden gate*, *kwai*, *screeching halt*, and *waldo* mRNA results in cell division failure due to defects in one or more of the following processes: centrosome duplication and assembly, formation of bipolar spindles, furrow formation, chromosome segregation, DNA stability, karyokinesis, and cytokinesis (Lindeman and Pelegri, 2010; Pelegri, 2003). For example, *aurora* kinases are pertinent regulators of mitosis since they play essential roles at various stages of mitosis, from mitotic entry to cytokinesis. It was found that *aurora-A* is essential for the intactness of the centrosome and establishment of the bipolar spindle assembly, and the lack of this transcript leads to the mitotic arrest of cells. On the other hand, *aurora-B* is not necessary for spindle formation, but instead is essential for furrow formation due to its regulation of cytoskeletal organization. Thus, in embryos lacking this mRNA, the cells do not divide properly and form a syncytium, following which the embryo subsequently dies.

From the onset of the first cleavage to the initiation of ZGA and even thereafter, various maternally-provided transcripts play critical roles in the regulation of early embryonic development such as axis polarity (dorsal/ventral and anterior/posterior), development of the germ plasm and subsequent germ line stability, and activation of the embryonic genome. The functions of the maternally-provided RNAs extend beyond ZGA and they are necessary for proper development of the later embryo, including body patterning. As mentioned above, mRNAs including the vegetally-positioned *swirl*, *unt8a*, and *grip2a* in addition to β -catenin, *dkk1*, and *tkk* among others have been found to be involved in the specification and establishment of the dorsal/ventral axis (Marlow, 2010). It has been shown that the Wnt signaling pathway is essential for dorsal axis determination, and a decrease in the mRNAs for members of this pathway, including *unt8a*, β -catenin, *dkk1*, and *tkk*, results in ventralization of the embryo demonstrated by the lack of notochord, neural tube, and trunk somites. In fact, the maternally-derived Wnt pathway is also essential for anterior/head formation, although only before MBT, since maternal Wnt transcripts present before MBT induces head formation, but blocks it afterwards. This was verified by embryos that lack maternal *headless* transcripts, which encodes a repressor of Wnt target genes and show complete loss of eyes, forebrain, and part of the midbrain with cranial-specific defects. Thus, it seems that although the *headless* mRNA is maternally-provided and accumulated in the egg during oogenesis, differential localization of it relative to the transcripts of the Wnt target genes enables activation of Wnt signaling before MBT and its repression afterwards. The *headless* transcript is widely distributed throughout the embryo, but excluded from the dorsolateral margin where the Wnt components are localized, during early development.

In addition to these, there are transcripts that are involved in the development of the endoderm and mesoderm layers, which are precursors to the major organs. It is well-known that factors belonging to the TGF- β superfamily play important roles in endoderm and mesoderm specification and patterning. Early nodal signaling relies on the maternally-provided *omesodermin-a* transcript, which subsequently activates embryonically-transcribed nodal genes that are necessary for initial mesodermal and endodermal fate specification. In addition, *activin* mRNA is also necessary for mesoderm induction and axis formation as demonstrated by mutants that have reduced maternal *activin* that show posteriorization of the head and diminished or delocalized notochord formation. There are also certain transcripts that are important for the differentiation of specialized cell types such as those in the eye, chromatophores (*gart* and *paics*) as well as primordial germ cells (*bucky ball*, *kif5Ba*, *vasa*, *nanos1*, *brul*, and *dazl*). A common characteristic in teleost fishes is that the primordial germ cells are frequently involved in ovary development and/or maintenance such that lack of maternal mRNAs for genes that are required for germ cell differentiation and maintenance undergo masculinization and become sterile males or have underdeveloped ovaries/oocytes as demonstrated by mutants that lack maternally-provided *vasa* or *nanos1*, respectively.

In addition, there are maternally-provided mRNAs that are involved in the activation of the embryonic genome, as evidenced by the function of *npm2b*. It was shown that *npm2b* transcript is stored in the egg in large amounts and is necessary for the activation of and subsequent transcription from the embryonic genome since its deficiency leads to arrest at the MBT and eventual death (Fig. 3) (Bouleau *et al.*, 2014). This may be due to the functions of Npm2b as a histone chaperone, which is involved in sperm DNA decondensation, and in the promotion of essential embryonic gene expression. Another important event at MBT that signals the transition is the clearance of maternal RNAs and, as mentioned above, miRNA-430 plays a large role in this as certain maternally-provided transcripts, such as those for *dicer* and *ago2*, which regulate the activity of miRNAs, were found to be important for the degradation of maternal RNAs and their inhibition leads to morphogenesis defects similar to the miR-430 mutants (Schier and Giraldez, 2006).

Fig. 3 Development at different stages of wildtype and *npm2b*-deficient zebrafish embryos. Representative images showing the developing zebrafish embryo at different stages of embryogenesis: 6, 7, and 10 h post-fertilization (hpf). Wildtype embryos were used to compare the embryos with *npm2b* inhibition, the latter of which demonstrated aberration in embryonic development whereby cell division was normal until 4 hpf, but was arrested thereafter until they eventually died between 12 and 24 hpf. Scale bar: 250 μ m.

There are some distinct differences between the reproduction of fish and tetrapods, such as the external development of the embryo and presence of yolk as primary nutrient, that necessitate the addition of different types of maternal transcripts in the egg. The externalized nature of the egg renders it more susceptible to damage at the structural level as well as at the DNA level, thus, mRNAs for *zp2* and *zp3* that encode structural proteins of the chorion membrane as well as those that encode components of the DNA repair machinery are found in the egg. Further, since the yolk is the primary source of nutrition for the embryo until they hatch and find food for themselves, many yolk-processing mRNAs (*cathepsins B, D, F, L*, and *LPL*), which are mostly enzymes that breakdown the yolk proteins to produce metabolically active substances, are also present (Kwon *et al.*, 2001). In addition, it has been revealed that the fertilized egg carries many immune system-related mRNAs such as those that encode members of the chemokine signaling/regulatory pathway, mhc class 2 chains, complement factors, T-cell receptor signaling pathway, and innate immunity.

Maternally-Inherited Small Non-Coding RNAs

As compared to mRNAs, small regulatory non-coding RNAs (ncRNA) have been much less extensively studied before MBT and only until very recently have researchers gained interest in their function in early fish embryos. Indeed, most studies focused on their role during oogenesis or in the maternal mRNA clearance at MBT. However, in recent years several studies using new generation sequencing revealed a large repertoire of miRNAs expressed in unfertilized eggs in rainbow trout or in zebrafish early embryo (Presslauer *et al.*, 2017), which may be stocked as maternal RNAs. At the present time, there is no information on the localization of miRNAs in the developing, mature or fertilized fish egg. However, maternally-inherited miRNAs appear to be rapidly down-regulated during the transition from maternal to embryonic gene expression, raising the possibility that they are subject to similar forms of regulation as maternally-inherited mRNAs for ZGA.

Regarding the role of these regulatory RNAs, little information has been obtained to date. A few functional studies were initiated in zebrafish to elucidate the role of single miRNAs during early development. The miR-34 is one of the first and a rare maternal miRNA for which a role has been identified. To this aim, the activity of miR-34 was inactivated in fertilized eggs, which led to defects in neural development and deregulation of the key Notch signaling pathway. This shed light on the importance of miR-34 in the regulation of embryonic genes necessary for neurogenesis after MBT. Another example is the miR-92a-3p, whereby its mature miRNA was inactivated in oocytes. It was observed that resulting embryos were arrested as early as the one-cell stage. Such a phenotype indicates that the maternally-inherited miR-92a plays a critical role during the first events that occur just after

fertilization. Reasons to explain this phenotype may be a failure in meiosis completion of the oocyte (oocyte activation), a lack of fertilization or a failure of the onset of the first cell cycle. In the future, identification and analysis of genes targeted by miR-34 and miR-92a will provide essential clues to identify cellular processes that are regulated.

Besides miRNAs, another class of small non-coding RNAs, called Piwi-interacting RNA (piRNA), was also detected in unfertilized eggs. Sequencing data revealed that, compared to miRNA, piRNA contribute to a high proportion of the total RNA, constituting about 80% of small RNAs present in the zebrafish unfertilized embryo (Presslauer *et al.*, 2017). However, despite the abundance of the maternally-inherited piRNAs, their role in the early embryo remains unknown. Nonetheless, piRNAs are known to be mainly involved in the regulation of transposon activity and in the genome protection, and to be essential for maintenance of germ cells and meiosis in zebrafish, which suggest that they may also function as maternal regulators of embryogenesis.

Conclusions

Thus, the maternally-provided RNAs in fish function to lay down the foundation for the body plan of the embryo, regulate the first few cell divisions, facilitate the development of the germ-line cells, coordinate the activation of the embryonic genome, degradation of its own RNAs, as well as proper embryogenesis after MBT, and provide primary defense and nutrition mechanisms to give the embryo a good head start in life. What has been described here is just the tip of the iceberg, and extensive studies are being carried out worldwide to understand in more detail the localization, regulation and function of more maternally-provided mRNAs as well as the roles of the miRNAs, piRNAs and other ncRNAs.

Maternal RNAs, *Drosophila*

Introduction

In most species, the newly formed zygote is transcriptionally silent, therefore the very first steps of embryogenesis depend on maternal reserves, namely mRNAs and proteins produced by the mother and loaded into the egg to kick-start embryonic development. The control of development then switches from the maternal to the zygotic genome during the maternal-to-zygotic transition, which includes the massive decay of maternal mRNAs and the transcriptional activation of the zygotic genome (Fig. 1; Laver *et al.*, 2015). In *Drosophila*, the oocyte is transcriptionally silent, and the maternal mRNAs are synthesized during oogenesis by specialized germ cells called the nurse cells. *Drosophila* ovaries are composed of about 16 ovarioles that are egg production units containing egg chambers of increasing maturity from anterior to posterior (Fig. 2(A)). Oogenesis is divided into 14 stages, stage 14 being the mature egg. It starts with the asymmetric division of a germline stem cell located at the anterior tip of an ovariole, to give rise to another stem cell and a daughter cell that undergoes differentiation. The daughter cell divides four times with incomplete cytokinesis to produce a cyst composed of 16 interconnected germ cells. One of these 16 cells adopts an oocyte fate, whereas the other 15 germ cells undergo polyploidy and become nurse cells (Fig. 2(A); Bastock and Johnston, 2008). Nurse cells produce large amounts of maternal mRNAs and proteins that are transported to, and towards the end of oogenesis, “dumped” into the oocyte -when nurse cells contract and pour their content into the oocyte-. This occurs through ring canals that connect nurse cells to the oocyte and to each other. RNA profiling in unfertilized eggs has shown that around 50% of the protein-coding genome is represented in maternal mRNAs (Thomsen *et al.*, 2010). Many of them undergo cytoplasmic controls that involve regulation of mRNA stability, localization and translation, three highly interconnected processes. In particular, 60% of maternal mRNAs present in the egg are degraded to some extent, at the maternal-to-zygotic transition (Thomsen *et al.*, 2010). An important mechanism underlying the regulation of maternal mRNAs involves the control of mRNA poly(A) tail lengths (Weill *et al.*, 2012). Virtually all mRNAs acquire a poly(A) tail at their 3' end through a nuclear cotranscriptional reaction called cleavage and polyadenylation. The poly(A) tail plays a major role in mRNA stability and translation and can be regulated in the cytoplasm: mRNA poly(A) tail shortening by deadenylation induces mRNA decay and/or translational repression. In oocytes, maternal mRNAs can be stored as dormant (untranslated) mRNAs with short poly(A) tails; their translation can then be activated at specific developmental stages by poly(A) tail lengthening through cytoplasmic polyadenylation (Barckmann and Simonelig, 2013). A recent study analyzing mRNA poly(A) tail lengths and translational efficiency at genome-wide level, using new technologies for poly(A) tail sequencing and ribosome-footprint profiling, confirmed that translation efficiency depends on mRNA poly(A) tail length in stage 14 oocyte and early embryo, up to gastrulation when this coupling disappears (Eichhorn *et al.*, 2016). This study also revealed that, although cytoplasmic polyadenylation is massive at these stages, the specific regulation of each mRNA is more dependent on deadenylation.

Specific maternal mRNAs are highly regulated and play essential roles in the development of the future embryo; their regulation has been the focus of many genetic studies and they can be used as model systems to illustrate a wide panel of mRNA regulation.

Maternal-to-Zygotic Transition (MZT) in the *Drosophila* embryo

Fig. 1 Maternal-to-zygotic transition in the *Drosophila* embryo. Profiles of unstable maternal mRNAs (green) and of zygotic mRNAs (orange) are schematized. Smg, piRNAs and the CCR4-NOT complex are part of the maternal pathway of mRNA decay, whereas the *miR-309* cluster is part of the zygotic pathway. The role of CCR4-NOT in the zygotic pathway of mRNA decay is likely, but has not been formally addressed. The dashed vertical line indicates the time at which the bulk of zygotic transcription starts. Time is indicated in hours after egg deposition at 25°C.

Fig. 2 *Drosophila* oogenesis and the role of maternal mRNAs in embryonic patterning. (A) Schematic representation of *Drosophila* oogenesis. An ovary is composed of about 16 ovarioles. An ovariole (A) contains egg chambers of increasing maturity from anterior (left) to posterior (right). The germarium is present in the anterior-most region of the ovariole. It contains two to three germline stem cells that are anteriorly localized. Each germline stem cell divides asymmetrically to produce a new stem cell and a daughter cell that undergoes four rounds of synchronous division with incomplete cytokinesis, producing 16 germ cells interconnected by ring canals. Egg chambers are composed of these groups of 16 germ cells – 15 nurse cells and one oocyte – surrounded by an epithelium of somatic follicle cells. Nuclei of nurse cells and of the oocyte are in blue. Egg chambers develop through 14 morphological stages (indicated above egg chambers) to produce mature eggs (stage 14). Throughout oogenesis, nurse cells provide maternal mRNAs and proteins to the oocyte through ring canals. These maternal components are required for the development of the oocyte and the future embryo. (B) Schematic representation of mRNA and protein localization for *bcd*, *grk*, *osk* and *nos* in stage 10 oocyte and early embryo. *bcd*, *grk* and *osk* mRNAs localize during mid-oogenesis, while *nos* mRNA localization occurs at later stages. mRNA localization is coupled to translational control such that protein synthesis is localized. The specific localization of *bcd* and *nos* mRNAs at the anterior and posterior poles, respectively, generates Bcd and Nos opposite protein gradients that shape the anterior-posterior axis of the embryo. Axis orientation is indicated at the top: A, anterior, P, posterior, D, dorsal, V, ventral.

Function of Maternal mRNAs: Establishment of the Oocyte and Embryonic Polarity

Maternal mRNAs and their post-transcriptional regulation play a key role in meiotic progression and regulation of cell cycle in the oocyte and early embryo. Oocyte maturation (meiotic progression from prophase to metaphase I) that takes place in stage 12–13 oocyte is accompanied by poly(A) tail lengthening of a large set of maternal mRNAs and large-scale changes in the proteome (Laver *et al.*, 2015).

Another major function of maternal mRNAs is to establish the polarity of the *Drosophila* embryo, which already takes place in the oocyte. Four maternal mRNAs, *oskar* (*osk*), *nanos* (*nos*), *bicoid* (*bcd*) and *gurken* (*grk*) play key roles in embryonic axis specification

(Lasko, 2012). The corresponding genes were identified through genetic screens: mothers mutant for these genes produce embryos lacking embryonic structures. These maternal mRNAs are transported along microtubules from the nurse cells to the oocyte, during early stages of oogenesis, through the ring canals. Localization of these mRNAs become highly asymmetric from mid-oogenesis (stage 9) and this localization coupled to translational regulation underlies axis specification (Fig. 2(B)). The anterior-posterior axis is established through the localization of *bcd* mRNA to the anterior pole of the oocyte and the localization of *osk* and *nos* mRNAs to the posterior pole. *osk* mRNA is translated when it reaches the posterior pole during mid-oogenesis. Osk protein is the primary determinant of the germ plasm, a specialized cytoplasm that is required for germ cell development at the posterior pole of the oocyte (Lehmann, 2016). Large RNA granules, so-called polar granules, containing mRNAs, small RNAs and proteins form in the germ plasm. Polar granules contain mRNAs encoding germ cell determinants and are essential for germline specification. Nos is one of those germ cell determinants, and is also required for abdominal development. Nos protein is expressed as a posterior to anterior gradient generated from *nos* mRNA localized in the germ plasm at the posterior pole. Osk is involved in the stabilization and translation of germ cell mRNAs, including *nos*, in the germ plasm. Osk is therefore essential for both posterior patterning and specification of the germline lineage in the embryo (Fig. 2(B)).

Although localized at the anterior pole of the oocyte during mid-oogenesis, *bcd* mRNA is translated only after egg activation -when the mature stage 14 oocyte passes through the oviduct, prior to fertilization-. Its translation depends on poly(A) tail elongation. Bcd protein is produced as a gradient from the anteriorly localized mRNA. This gradient of Bcd acting both as a transcription factor and a translational repressor, initiates a cascade of zygotic gene expression that directs anterior-posterior patterning of the embryo.

Grk is required in establishing both the anterior-posterior and dorsal-ventral axes during oogenesis. Grk is an epidermal growth factor receptor (EGFR) ligand secreted from the oocyte to locally activate EGFR in the adjacent somatic cells that surround the oocyte, the follicle cells. During early oogenesis, Grk plays a role in establishing anterior-posterior polarity by signaling to a posterior subpopulation of follicle cells to adopt a posterior fate. During mid-oogenesis, *grk* mRNA localizes to the antero-dorsal corner of the oocyte and produces localized protein that specifies the dorsal-ventral axis, by inducing a dorsal fate in the closest follicle cells (Fig. 2(B)).

Regulation of Maternal mRNAs in Oocytes

Localization of Maternal mRNAs in Oocytes

mRNA localization is a widespread process to generate cell asymmetry in diverse biological contexts, and it is instrumental for setting up axes in the *Drosophila* embryo. Several mechanisms are at play for localizing in the oocyte mRNAs that are required for axis formation, and the whole process is very complex and highly regulated. Extensive genetic and molecular studies of mRNA localization identified common principles: localization depends on sequence elements that are often present in mRNA 3'UTRs and on proteins that bind these elements; RNA localization elements often form stem-loop structures and are often repeated and redundant; distinct localization elements on the same mRNA can mediate distinct steps in localization (Martin and Ephrussi, 2009).

A common mechanism for mRNA localization in the oocyte corresponds to active transport along microtubules. The microtubule network in the nurse cells and oocyte is complex and reorganizes several times during oogenesis. Live-imaging studies have been essential to shed light on the mechanisms of mRNA transport and the cytoskeletal organization (Becalska and Gavis, 2009). An important tool for these studies, which was first developed in yeast and later adapted to *Drosophila*, is the MS2 system: an mRNA is GFP-tagged *via* the tethering of the bacteriophage MS2 coat protein fused to GFP, to MS2 coat protein binding sites inserted into the mRNA 3'UTR. The MS2 system allows visualization of mRNA movements (Becalska and Gavis, 2009; Bertrand *et al.*, 1998; Forrest and Gavis, 2003).

During early oogenesis, maternal mRNAs are transported from nurse cells to the oocyte through the ring canals, on microtubules that extend into nurse cells, from a microtubule-organizing center (MTOC) localized in the oocyte. mRNA transport proceeds towards microtubule minus ends driven by the dynein motor complex. Two interacting proteins Egalitarian and Bicaudal-D make the link between mRNAs, bound to Egalitarian, and the dynein complex interacting with Bicaudal-D through dynactin (Lasko, 2012) (Fig. 3(A)). At stage 7 of oogenesis, microtubules reorganize for a less organized network, but transport from nurse cells to oocyte remains dynein-dependent (Becalska and Gavis, 2009).

mRNAs localized to the posterior pole must travel long distances of more than 50 μm . mRNA live-imaging analyses have shown that, at mid-oogenesis (stages 9–10), the microtubule network within the oocyte is largely randomly organized, with a slight bias towards plus ends at the posterior pole. Posterior *osk* mRNA localization takes place through kinesin-directed transport towards plus ends of microtubules (Fig. 3(B)). Accumulation at the posterior pole is achieved through transport along this slightly biased microtubule network, over a period of several hours (Becalska and Gavis, 2009). Genetic studies have identified a number of proteins involved in *osk* mRNA posterior localization, including Staufen, Hrp48, and subunits of the exon-junction complex. This complex is recruited to the mRNA during splicing, thus revealing that nuclear events can play essential roles in mRNA cytoplasmic localization (Lasko, 2012; Lehmann, 2016; Fig. 3(B)).

The localization of *bcd* mRNA at the anterior pole of the oocyte proceeds through several steps, the first of which requires the Exuperantia protein that was proposed to select a subpopulation of microtubules polarized towards the anterior cortex for dynein-directed transport. At later stages (stage 12), *bcd* mRNA localization requires Swallow and the double strand RNA binding

Fig. 3 Mechanisms of maternal mRNA transport during *Drosophila* oogenesis. Molecular mechanisms involved in the localization of *osk*, *bcd*, *grk* and *nos* mRNAs at different stages of oogenesis are schematized. For all panels, a scheme of an egg chamber is on the left; and a scheme showing the factors involved in localization is on the right. Nuclei of nurse cells and of the oocyte are in blue; microtubules and actin microfilaments are in grey; black arrows indicate mRNA movements. (A) Dynein-directed transport of mRNAs along microtubules in nurse cells during early oogenesis (stages 1–6). Egl and Bic-D proteins directly recruit mRNAs to the dynein-dynactin complex. (B) *osk* mRNA transport along microtubules in the oocyte during mid-oogenesis. *osk* is transported towards plus ends of microtubules with kinesin. Microtubules are largely randomly organized in the oocyte, with a slight bias for plus ends towards the posterior pole. RNA binding proteins and other components required for *osk* mRNA transport are schematized. The exon-junction complex (EJC) is deposited on the mRNA upon splicing in nurse cell nuclei. (C) *bcd* and *nos* mRNA localization in late stage oocytes. A stage 12 egg chamber is schematized. At this stage, nurse cells contract to dump their cytoplasm into the oocyte. *bcd*

protein Staufen, and depends on continuous dynein-mediated transport on microtubules organized from the anterior cortex of the oocyte (Fig. 3(C)). At late oogenesis (stage 14), *bcd* mRNA localization switches from continuous active transport to stable anchoring to the cortical actin cytoskeleton. This actin-dependent anchoring is maintained until egg activation, when *bcd* mRNA is dispersed (Becalska and Gavis, 2009).

In contrast to *bcd* and *osk*, *nos* mRNA localization does not involve transport along microtubules. *nos* mRNA localization to the posterior pole of the oocyte takes place during late oogenesis (stages 11–13), following the onset of nurse cell dumping. Cytoplasmic streaming (cytoplasmic flow into the oocyte based on microtubules parallel to the oocyte cortex) and nurse cell dumping produce a rotating flow of cytoplasm mixing nurse cell and oocyte contents. *nos* mRNA localization is achieved via posterior anchoring of the pool of mRNA that goes through the germ plasm during this cytoplasmic movement (Becalska and Gavis, 2009; Forrest and Gavis, 2003; Fig. 3(C)). Anchoring depends on actin cytoskeleton and its reorganization involving the longer of two Osk protein isoforms. This localization mechanism by diffusion and anchoring is used for posterior localization of a number of maternal mRNAs enriched in the germ plasm, and which encode proteins required for germ cell development. *osk* mRNA itself follows this localization process during late oogenesis. Novel quantitative imaging approaches to follow single mRNA molecules have shown that germ cell mRNAs (except *osk*) travel as single mRNA molecules in small particles, which then co-assemble in the germ plasm into large heterogeneous RNA granules containing different mRNAs: the polar granules (Lehmann, 2016; Little et al., 2015; Trcek et al., 2015). Recent studies identified Aubergine (Aub) protein as an important component of the posterior trapping complex, involved in direct interaction with germ cell mRNAs (Barckmann et al., 2015; Vourekas et al., 2016; Fig. 3(C)).

Translational Control of Maternal mRNAs in Oocytes

To achieve cell polarity through mRNA localization, an essential point is the coupling between localization and translational regulation: namely, translation must be repressed during transport, localization, or where localization is incomplete, and activated upon final localization. This coupling occurs by either of two mechanisms: (i) the presence of translational regulators together with localization factors on mRNAs during the localization process, or (ii) the dual role of some regulator proteins in both mRNA localization and translational control.

bcd mRNA translation is strictly repressed in oocytes and activated at egg activation. Cytoplasmic polyadenylation is involved in translation activation, however, *bcd* poly(A) tail length alone cannot explain the tight translational repression in the oocyte (Eichhorn et al., 2016). Thus, additional mechanisms should be involved, which have not yet been addressed.

osk mRNA translational control has been extensively studied. Osk protein is specifically synthesized at the posterior pole of the oocyte, starting during mid-oogenesis at stage 9, upon *osk* mRNA localization. An important component of the translational repressor complex is the Bruno protein that binds several elements in *osk* 3'UTR. Bruno represses *osk* mRNA translation by two mechanisms: (i) it induces the formation of large mRNA particles that are inaccessible to the translation machinery, and (ii) it recruits the Cup protein, which can directly affect translation through its interaction with the cap binding translation initiation factor eIF4E, thus preventing eIF4E-eIF4G interaction and translation initiation. Cup can also recruit the CCR4-NOT deadenylation complex (Lasko, 2012; Fig. 4(A)). CCR4-NOT is a conserved complex composed of eight proteins in *Drosophila*, including two deadenylases (Temme et al., 2014). Deadenylation is the first step of mRNA decay. However, in oocytes as opposed to most other cell types, deadenylation does not lead to immediate mRNA decay; instead deadenylated mRNAs can be maintained translationally repressed for re-activation at later developmental steps. Me31B is another translational repressor of *osk* mRNA, in complex with Cup and eIF4E. Additional translational repressors include PTB (polypyrimidine tract binding protein) and Hrp48 that is also involved in *osk* mRNA localization.

osk mRNA translation is locally activated at the posterior pole of the oocyte. Orb, the RNA binding protein homolog of CPEB (Cytoplasmic Polyadenylation Element Binding protein), plays a role in this process. Orb interacts with two poly(A) polymerases, PAP (poly(A) polymerase) and Wispy, the cytoplasmic poly(A) polymerase. Posterior translational activation of *osk* mRNA at mid-oogenesis depends on poly(A) tail elongation by PAP (Lasko, 2012; Fig. 4(A)). Wispy is required for polyadenylation of a large set of maternal mRNAs at late stages of oogenesis. Interestingly, Bruno, the translational repressor of *osk* mRNA during its transport, contributes to *osk* translational activation at the posterior pole, as does Staufen, a component of the *osk* mRNA transport machinery.

Regulation of Maternal mRNAs in Embryos

Maternal mRNA Decay During the Maternal-to-Zygotic Transition – Role of Small Non-Coding RNAs

In early embryos, maternal mRNAs undergo a massive decay during the maternal-to-zygotic transition (Fig. 1). Genome-wide transcriptome analyses have shown that 60% of maternal mRNAs are significantly degraded during this period. The comparison of maternal mRNA decay in fertilized embryos and activated unfertilized eggs, without zygotic transcription, revealed that maternal mRNA decay involves two pathways: an early pathway encoded maternally, and a later pathway encoded by the zygote, taking place

localization to the anterior involves continuous dynein-directed transport along microtubules (small black arrows), and the Staufen (Stau) RNA binding protein. Cytoplasmic streaming and nurse cell dumping induce a rotating flow of cytoplasm in the oocyte (circular black arrow) allowing diffusion in the oocyte of a pool of maternal mRNAs, including *nos*. These maternal mRNAs are anchored at the posterior pole via actin microfilaments, when they go through the germ plasm during their rotating movement with the cytoplasm. The long Osk protein isoform (Osk-L) is involved in actin remodeling. Aub binds maternal mRNAs, colocalizes with the Wispy poly(A) polymerase in the germ plasm and is present in polar granules together with Tudor, Vasa and Osk short isoform. The comb represents a piRNA, required for Aub binding to mRNA.

Fig. 4 Translational control coupled to mRNA localization in the oocyte and embryo. (A) Translational regulation of *osk* mRNA in the oocyte during mid-oogenesis. Bruno, Cup and Me31B are translational repressors of *osk* mRNA. The role of the CCR4-NOT complex in *osk* mRNA translational control has not been directly tested (indicated by a question mark). Its implication is suggested from Cup interaction with the NOT1 subunit of CCR4-NOT in *Drosophila* S2 cells, and the direct interaction between NOT1 and the human homolog of Me31B. Cup can repress translation through binding to eIF4E (blue inhibitory arrow). Bruno binds to several sites called Bruno response elements (BREs: striped boxes) in *osk* 3'UTR. The 3'-most BRE is involved in both translational repression and activation. The Orb RNA binding protein is in complex with both poly(A) polymerase (PAP) and Wispy in the ovary, but cytoplasmic polyadenylation depends on PAP during mid-oogenesis (blue arrow). Translation repression takes place during *osk* mRNA transport, whereas translation is activated at the posterior pole. *osk* mRNA is in purple; Osk protein is represented by black dots. (B) mRNA decay and selective stabilization coupled to translational control of *nos* mRNA in the embryo. *nos* mRNA localization by diffusion and anchoring is inefficient, leading to high amounts of *nos* mRNA (light blue) in the soma, in addition to its accumulation (dark blue) in the germ plasm. In pre-MZT embryos, Smg binds to stem loop structures in *nos* 3'UTR, the Smg recognition elements (SREs). Aub binds to *nos* 3'UTR through complementary piRNAs (comb). Smg, CCR4, Aub and Ago3 are found in complex in embryos and are involved in *nos* mRNA deadenylation in the somatic part of the embryo. Cup bound to Smg could prevent translation via its binding to eIF4E (blue inhibitory arrow). However *nos* translational repression is independent of the 5' cap and involves mRNA coating by Me31B and TraI. The zygotic machinery of maternal mRNA decay involves miRNAs (comb) from the *miR-309* cluster. The protein interactions are drawn from interactions shown in other contexts, but not yet validated in the *Drosophila* embryo (indicated by a question mark). Most mRNA targets of miRNAs also undergo decay by the maternal pathway, indicating that both pathways cooperate in mRNA decay. The maternal pathway can implicate Smg or other RNA binding proteins (RBP). In addition, RNA binding proteins such as Pum are also involved in the zygotic pathway of mRNA decay (not shown). In the germ plasm, Osk binds Smg and this prevents Smg binding to *nos* mRNA. CCR4 is depleted from the germ plasm. Aub bound to *nos* mRNA through piRNAs (comb) colocalizes and interacts with Wispy, allowing poly(A) tail elongation, localized stabilization and translation (blue arrow), which generates the Nos protein gradient (blue dots). Aub interacts with Tudor and is present in polar granules with Vasa and Osk.

after zygotic transcription. Maternal mRNAs can be degraded by either of these two pathways or by both pathways together, leading to different dynamics of mRNA decay (Fig. 1).

Maternal mRNA decay by the maternal machinery depends on deadenylation by the CCR4-NOT deadenylation complex. This complex can act unspecifically on all mRNAs, and specificity is achieved through its recruitment to sequence elements in mRNAs, by RNA binding proteins or small non-coding RNAs binding these elements. An important actor in this decay is the RNA binding protein Smaug (Smg) that binds about two-thirds of unstable maternal mRNAs and recruits CCR4-NOT (Barckmann and Simonelig, 2013; Fig. 4(B)). The timing of the decay is determined by Smg expression that peaks between 30 min and 3 h of embryonic development.

nos mRNA has been used as a paradigm to follow maternal mRNA decay during the maternal-to-zygotic transition. *nos* is posteriorly localized by the mechanism of diffusion and anchoring during late oogenesis. This mechanism is very inefficient and a huge fraction of *nos* mRNA (calculated to be 96%) remains unlocalized in the whole embryo. This pool of *nos* is deadenylated by the CCR4-NOT complex recruited to *nos* 3'UTR by Smg, which leads to its decay during the first hours of embryogenesis. Further analyses of *nos* mRNA deadenylation identified a specific class of small non-coding RNAs, the Piwi-interacting RNAs (piRNAs), as components of the maternal machinery of maternal mRNA decay. The piRNA pathway is an RNA silencing pathway that has been found in the germline of many species. piRNAs are non-coding RNAs of 23–30 nt, which like microRNAs (miRNAs), are loaded into specific Argonaute proteins, so-called PIWI proteins, and interact with their target mRNAs by complementarity to silence them. This can occur *via* endonucleolytic cleavage of the target mRNA by PIWI proteins (Senti and Brennecke, 2010; Weick and Miska, 2014). The piRNA pathway plays a crucial role in the repression of transposable elements in the germline and indeed, a large part of piRNAs are produced from transposable element sequences. piRNAs are produced in the nurse cells in the ovary and transferred to the oocyte while loaded into PIWI proteins. Therefore, piRNAs are present in the early embryo. Strikingly, a role of the piRNA pathway has been established in the decay of *nos* mRNA in the embryo. piRNAs produced from transposable elements target *nos* 3'UTR and guide interactions with the PIWI proteins Aub and Argonaute 3 (Ago3), which, together with Smg, contribute to recruitment of the CCR4-NOT deadenylation complex (Fig. 4(B)). This regulation of *nos* mRNA by piRNAs is required for embryonic patterning, thus identifying a biological function of transposable elements in *Drosophila* development (Barckmann and Simonelig, 2013). Aub was then shown to directly bind several hundred maternal mRNAs in the early embryo, and to be involved in the decay of a large proportion of them. Aub induces decay either through deadenylation by CCR4-NOT, or by direct cleavage through its endonucleolytic activity (Barckmann *et al.*, 2015).

Maternal miRNAs are also present in the embryo and are likely to be involved in maternal mRNA decay, since miRNA target sites are found in mRNAs degraded by the maternal pathway. However, to date, the role of miRNAs in the maternal pathway of maternal mRNA decay has not been formally demonstrated.

In contrast, miRNAs are a major component of the zygotic pathway of maternal mRNA decay. The *Drosophila* *miR-309* cluster which produces eight miRNAs is highly expressed at the onset of zygotic genome activation and induces the decay of hundreds of maternal mRNAs (Barckmann and Simonelig, 2013). How miRNAs induce maternal mRNA decay has not been addressed. However, in many biological contexts, RNA silencing by miRNAs involves deadenylation by CCR4-NOT and another general deadenylation complex, PAN2-PAN3. miRNAs are loaded into Argonaute proteins and these proteins directly interact with proteins of the GW182 family, which in turn can recruit both deadenylation complexes through direct protein interactions. These interactions, which are conserved from *Drosophila* to mammals, are likely to be involved in maternal mRNA decay by miRNAs (Fig. 4(B)). Maternal mRNA decay by Smg is indirectly involved in zygotic genome activation and expression of the *miR-309* cluster, thus reflecting an interplay between the maternal and zygotic pathways of maternal mRNA decay.

RNA binding proteins have also been identified in the zygotic machinery of maternal mRNA decay. Pumilio (Pum) is involved in the degradation of *bcd* mRNA that is degraded by the zygotic pathway. Brain tumor (Brat), another RNA binding protein, first described as a co-factor of Pum, targets maternal mRNAs *via* both the early and late pathways of mRNA decay. Both Pum and Brat are thought to act by directly recruiting the CCR4-NOT deadenylation complex (Laver *et al.*, 2015).

Localization of Maternal mRNAs in Embryos by Selective Stabilization

Strikingly, when genome-wide analyses of maternal mRNA decay in embryos are compared with expression patterns of the same mRNAs using large-scale RNA *in situ* hybridization, a link between maternal mRNA decay and localization to the posterior pole becomes apparent. This indicates that mRNA decay can be spatially regulated and result in posterior mRNA localization. As explained in the previous section, the mechanism of posterior localization by diffusion and anchoring, taking place during late oogenesis, is very inefficient. Posterior localization of these mRNAs is then reinforced in the embryo by decay and selective stabilization in the germ plasm. Studies of *nos* maternal mRNA in the embryo have shown that Osk is the major factor in mRNA stabilization in the germ plasm. Osk directly interacts with Smg and prevents the binding of Smg to *nos* mRNA. This precludes the recruitment of the CCR4-NOT deadenylation complex to *nos* mRNA and its deadenylation. This mechanism has the potential to apply to all Smg target mRNAs (Barckmann and Simonelig, 2013; Fig. 4(B)). Another important component in this spatial regulation of maternal mRNA decay is the PIWI protein Aub. Recent studies of Aub function revealed its dual role in maternal mRNA decay in the somatic part of the embryo and localization in the germ plasm. Aub binds germ cell mRNAs and is involved in their degradation in the somatic part of the embryo (Barckmann *et al.*, 2015). However, Aub accumulates in the germ plasm in the oocyte and embryo and was proposed to contribute to germ cell mRNAs anchoring at the posterior pole during late oogenesis (Vourekas *et al.*, 2016). In the embryo, Aub plays a role in selective stabilization of these mRNAs in the germ plasm,

by recruiting the Wispy poly(A) polymerase (Fig. 4(B)). Thus, Aub function switches in space from decay to stabilization through regulated interactions with the deadenylation and polyadenylation machineries (Dufourt *et al.*, 2017).

Another mechanism reduces mRNA decay at the posterior pole. The zygotic genome activation is delayed in the primordial germ cells, the first cells to form in the embryo, leading to a delay of mRNA decay by the zygotic pathway (Barckmann and Simonelig, 2013).

Translational Control of Maternal mRNAs in Embryos

Recent studies at genome scale have shown that in late stage oocytes and early embryos up to gastrulation, translation efficiency depends on poly(A) tail length, thus confirming the key role of this mode of translational control during early development (Eichhorn *et al.*, 2016). At these stages poly(A) tail lengths are determined by the balance between deadenylation and cytoplasmic polyadenylation occurring concomitantly on the same mRNAs.

nos mRNA proved to be also an excellent model to study translational control. *nos* mRNA localization by decay and selective stabilization, which is based on poly(A) tail length regulation, is highly coupled to translational control. The pool of *nos* mRNA present in the somatic part of the embryo is translationally repressed before its decay. This repression is instrumental for the development of anterior embryonic structures. In contrast, translation of the pool of mRNA localized and stabilized by polyadenylation in the germ plasm is activated. This generates the posterior to anterior gradient of Nos protein that is essential for the development of abdominal structures and germ cells. Smg was first identified as a translational repressor of *nos* mRNA. This Smg function is partially due to its role in deadenylation through the recruitment of the CCR4-NOT complex. Indeed, recent genome-wide studies revealed that translational repression by Smg strongly correlates with poly(A) tail shortening (Eichhorn *et al.*, 2016). Consistent with this, ectopic Nos protein accumulates in the somatic part of embryos mutant for the CCR4 deadenylase, showing the role of CCR4 in translational repression (Barckmann and Simonelig, 2013). Interestingly, the CCR4-NOT complex has been shown in other contexts to be involved in direct translational repression, in addition to its role in deadenylation. This CCR4-NOT function relies on a direct interaction between the translational repressor Me31B and the NOT1 subunit of the complex, described with human proteins (Temme *et al.*, 2014).

Smg interacts with Cup, which contributes to the recruitment of the CCR4-NOT complex. Cup can also directly inhibit translation through its binding to eIF4E and displacement of eIF4G. Recent *in vitro* analyses identifying the components of the *nos* mRNA translational repressor complex have shown that translational repression involves mRNA coating with Me31B and its co-factor Trailer hitch (Tral) (Gotze *et al.*, 2017; Fig. 4(B)).

Smg is involved in both *nos* mRNA decay and translational repression, therefore its interaction with Osk contributes to both localized stabilization and translational activation in the pole plasm. In addition, specific regulation through 3'UTR of germ cell mRNAs is involved in their temporal translational activation (Barckmann and Simonelig, 2013).

Conclusions

Drosophila has been a powerful model to establish the importance of maternal mRNAs in early embryogenesis, as well as to decipher the involved regulatory mechanisms. Early steps of development that take place before activation of the zygotic genome depend exclusively on maternal mRNAs and their regulation in oocytes and early embryos. This regulation can occur at a wide range of steps of the mRNA life in the cytoplasm, including transport, localization, stability and translation. The mechanisms underlying this regulation are also varied, and are determined by a combination of *cis* elements present in mRNAs and factors binding these elements. The widespread role of small non-coding RNAs in regulating numerous biological processes has emerged in the last decades. miRNAs play an important role in maternal mRNA decay in the embryo during the maternal-to-zygotic transition. The role of piRNAs was more surprising since these small RNAs were thought to specifically regulate transposable elements. piRNAs have an essential function in both the decay and posterior localization of maternal mRNAs in the embryo. Because a large part of these piRNAs are produced from transposable elements, this establishes transposable elements as important regulators of early developmental processes. piRNAs are produced in the ovary and provided maternally to the embryo, thus they are part of maternal reserves that play key roles in embryonic development.

Deciphering the mechanisms of maternal mRNA regulation has identified the central role of the CCR4-NOT complex that acts both as a deadenylating enzyme and a scaffold to recruit translational repressors. This complex can accommodate large sets of mRNAs through interaction with various RNA binding proteins, and is used at many developmental steps in different regulatory mechanisms.

Another aspect in the regulation of maternal mRNAs is the formation of granules containing mRNAs, proteins, as well as small RNAs in some cases. The assembly of maternal mRNAs as RNA granules is involved in several processes including mRNA transport and translational control. RNA granules are specifically important in the germ plasm. Polar granules are crucial for germ cell specification, and this function is conserved in several species (Voronina *et al.*, 2011). *Drosophila* polar granules contain Osk protein, germ cell mRNAs, translational repressors, as well as several components of the piRNA pathway, including Aub and the germ cell markers Vasa and Tudor. piRNAs are also present in polar granules where they have a major function in germ cell development and maintenance through mRNA regulation. Many questions regarding RNA granules and polar granules are open for future studies, including their relationships with translational repression and activation, or the recently recognized role of RNA binding protein phase transitions in granule formation (Uversky, 2017).

The *Drosophila* model should continue to be at the fore front to decipher mechanisms involved in maternal mRNA regulation, many of which are conserved in mammals.

Glossary

Atresia The process by which ovarian follicles are degraded with resorption of yolk for recycling.

Egg A fully mature and ovulated female gamete that is competent to undergo fertilization and in which the embryo develops. After ovulation, oocytes become eggs. Also termed an ovum.

Follicle growth The period of time from when somatic prefollicle cells envelop the primary oocyte (folliculogenesis) to the end of vitellogenic oocyte growth.

Oocyte Female germ cell that arises from an oogonium after the onset of meiosis.

Oogenesis Process by which oogonia become mature eggs (or ova), the female gametes.

Ovarian follicle An oocyte surrounded by supporting somatic cells and acellular materials. These include a monolayer of granulosa cells overlain by a theca made up of connective tissue and vasculature covered by a surface epithelium. A vitelline envelope (zona pellucida) is formed between interleaved microvilli projecting from the oocyte and granulosa cells; this structure becomes the outer protective chorion of the egg and embryo. The follicle ruptures at ovulation to expel the oocyte, which is now termed an egg. Postovulatory follicles may persist and produce reproductive hormones for some time after ovulation.

Ovarian maturation The series of events following resumption of meiosis and initiation of cytoplasmic maturation by fully-grown (postvitellogenic) oocytes until ovulation of fertilizable eggs. The process also includes maturation of the follicle cells (theca, granulosa cells) and their steroidogenic activities and communication with one another and with the oocyte.

Vitellogenesis In common usage – the stage of oocyte growth characterized by the formation of egg yolk precursor proteins in the liver and their deposition in the ooplasm in the form of yolk proteins. By strict definition – the process by which estrogens induce the liver to produce and secrete the major precursors to yolk proteins, vitellogenins.

Vitellogenin receptors Oocyte surface proteins involved in uptake of vitellogenins (Vtgs) by growing oocytes. Two types of Vtg receptors (Vtgrs) have been described, the ‘classical’ Vtgr, which is a variant of the somatic very low-density lipoprotein receptor (Vldlr), and the low density lipoprotein (Ldl) receptor-related protein 13, termed Lrp13.

Vitellogenins Major precursors to the egg yolk proteins. Vitellogenins (Vtgs) are synthesized and secreted by the liver under estrogen stimulation, transported in the blood to the ovary, taken up by growing oocytes via receptor mediated endocytosis, and cleaved into their product yolk proteins, which are stored in the ooplasm. Several different types of fish Vtg have been described.

Yolk The content of the ooplasm of the egg, which provides essential nutrients and other materials required by the developing embryo. In addition to the major yolk proteins derived from vitellogenin, yolk is made up of diverse mélange of components of maternal or endogenous origin, including RNAs, regulatory proteins (e.g. growth and transcription factors), several classes of lipids, vitamins, minerals, and hormones.

Yolk proteins In common usage - any protein in the yolk. By strict definition - products derived from vitellogenins that are stored in the ooplasm. These include lipovitellin (Lv), phosvitin (Pv), β' -component, carboxy-terminal component (Ct), proteolytic derivatives of these 5 major yolk proteins, and complexes formed between them.

Abbreviations

Apo B Apolipoprotein B

β' -c β' -component yolk protein derived from vitellogenin

Ct Carboxy-terminal component yolk protein derived from vitellogenin

FAA Free amino acids

FFA Free fatty acids

Ldl/LDL Low density lipoprotein

Ldlr/LDLR Low density lipoprotein (Ldl) receptor

Lpl Lipoprotein lipase

LLTP Large lipid transfer protein

Lrp13 LDL receptor-related protein 13, vitellogenin receptor that preferentially binds VtgAa in acanthomorphs

LRX+1 Vitellogenin receptor and Lrp13 variant in salmonids

Lv Lipovitellin – the major yolk protein derived from vitellogenin that carries lipids to the ooplasm

LvH Lipovitellin heavy chain
LvL Lipovitellin light chain
MtTp Microsomal triglyceride transfer protein
Pv Phosvitin yolk protein, mainly comprised of polyserine and heavily phosphorylated
RNA Ribonucleic acid
TGL Triacylglycerol (triglyceride)
Vldl/VLDL Very low density lipoprotein
Vldlr/VLDLR Very low density lipoprotein (Vldl) receptor
Vtg Vitellogenin, major yolk protein precursor
VtgAa Acanthomorph A-type vitellogenin Aa
VtgAar Vitellogenin Aa receptor – also termed Lrp13
VtgAb Acanthomorph A-type vitellogenin Ab
VtgAbr Vitellogenin Ab receptor – also termed Vtgr
VtgC C-type vitellogenin that is phosvitinless in teleosts
Vtgr Vitellogenin receptor
YP Yolk protein

Introduction

Growth of ovarian follicles can be divided into primary growth and secondary growth stages (Fig. 1). During primary growth, the oocyte initiates meiosis (arresting at prophase I) and engages in intensive synthesis of RNAs that will direct further oogenesis and

Fig. 1 Model depicting oogenesis in European sea bass, *Dicentrarchus labrax*. An oocyte enclosed by layers of supporting somatic tissues (granulosa cells and theca) is called a follicle. Primary growth oocytes enter 'secondary growth' and accumulate neutral lipids into droplets in their ooplasm. During vitellogenesis, lipid deposition continues as the oocyte accumulates yolk proteins, which are stored in the ooplasm as yolk granules. Fully-grown follicles undergo final maturation, which entails resumption of meiosis and cytoplasmic maturation of the oocyte, including fusion and dissolution of the yolk granules, coalescence of the lipid droplets, clearing of the ooplasm, and an increase in oocyte size due to uptake of water. Maturation is followed by ovulation of an egg capable of being fertilized. At any stage prior to ovulation, the follicle may undergo atresia (breakdown); the egg envelope is breached and granulosa cells enter the ooplasm to scavenge yolk proteins and lipids for recycling. Portions redrawn from Reading, B.J., Sullivan, C.V., 2011. Vitellogenesis in fishes. In: Ferrell, A.P. (Ed.), Encyclopedia of Fish Physiology: From Genome to Environment. The Reproductive Organs and Processes. Reference Module in Life Sciences 2011 ed. Maryland Heights, MO: Elsevier, pp. 635–646. Available at: <https://doi.org/10.1016/B978-0-12-374553-8.00257-4>.

early embryo development. Secondary oocyte growth involves prodigious accumulation of materials in the ooplasm, accounting for most of the final mass of the ovulated egg (Lubzens *et al.*, 2017). These include neutral lipids, sometimes apparent as droplets in the ooplasm, and phospholipid-rich yolk protein (YP) precursors called vitellogenins (Vtgs). Vtgs are synthesized by the liver in response to estrogen, transported in the bloodstream to the ovary, taken up by growing oocytes, and processed into YPs, which are typically stored in yolk granules (also termed globules or platelets) but sometimes in an amorphous compartment ('fluid yolk'). Proliferation of neutral lipid droplets evident in the ooplasm may precede detection of yolk granules and is sometimes referred to as 'previtellogenic' growth. Postvitellogenic follicles containing oocytes filled with lipid droplets, where present, and yolk granules or other types of inclusions bearing YPs, proceed to final maturation, followed by ovulation. At any stage of oocyte growth or maturation prior to ovulation, the follicle may undergo atresia (breakdown) with resorption of the yolk contents (Fig. 1). Limited atresia is a normal process by which females adjust their fecundity, but massive preovulatory atresia entails reproductive failure. Images of ovarian follicles of European sea bass (*Dicentrarchus labrax*) in primary growth or undergoing secondary growth at 'previtellogenic' and vitellogenic stages are provided in Fig. 2.

Composition of Vitellogenins and Yolk Proteins

Vitellogenins are massive proteins, ~300–600 kDa by weight, comprised of homodimers made up of two identical polypeptides, each consisting of a linear array of YP domains bearing phosphate, carbohydrate and lipid components (Fig. 3(A)). Lipids comprise ~20% of Vtgs by weight, primarily phospholipids with lesser quantities of triacylglycerol (Tgl), cholesterol and wax- or steryl-esters (Fig. 3(B)). Vtgs are rich in polyunsaturated fatty acids (~50% of total) providing fluidity to cell membranes in developing embryos. In species spawning demersal (sinking) eggs or floating eggs lacking prominent oil droplets, Vtgs are major carriers of lipids into oocytes, polar lipids (e.g. phosphatidylcholine) predominate in the yolk (~70%–90% of total), and overall lipid levels are usually low (<5% of wet weight). In species spawning pelagic (floating) eggs with large oil droplets, Vtg makes only a minor contribution to yolk lipids, and neutral lipids including Tgl and wax- or steryl esters, predominate. Very low density lipoprotein (Vldl) delivers Tgl to the ovary, from which free fatty acids (FFA) are cleaved by lipoprotein lipase (Lpl) to enter the ooplasm where they are used to synthesize the neutral lipids found in the oil droplets (Hiramatsu *et al.*, 2015). In addition to phosphate, carbohydrate and lipids, Vtgs are important carriers of iron, calcium, magnesium and other minerals, fat-soluble vitamins and related compounds (e.g. vitamins A and E, other retinoids, carotenoids), and hormones, such as thyroid hormones and cortisol that are

Fig. 2 Light micrograph of an ovary section from a vitellogenic European sea bass, *Dicentrarchus labrax*. Shown are a large mid-vitellogenic (MV) oocyte that is filled with yolk granules (yg) and lipid droplets (ld) and is enclosed in a well developed zona pellucida (zp) or egg envelope overlain by follicle cells (fc). Also shown are an early vitellogenic oocyte (EV) beginning to accumulate yolk granules peripherally, a pre-vitellogenic oocyte (PV) undergoing secondary growth and lacking definitive yolk granules, and several primary growth oocytes (PG). The sample was collected from a farmed female in late winter on the Southwest coast of Spain and subjected to routine histological procedures to obtain 3 μm paraffin sections stained with methylene blue-azure II to visualize the structures referenced above. Fig. 3 Structural features of vitellogenins in higher teleosts. (A) Model depicting the linear subdomain structure of native (dimeric) complete vitellogenins (VtgAa and VtgAb) and incomplete vitellogenin (VtgC) and their yolk protein products. The yolk proteins include lipovitellin (Lv) heavy chain (LvH) and Lv light chain (LvL), which transport lipids (indicated by brown half ovals), phosvitin (Pv), which is mainly polyserine and is highly phosphorylated (indicated by blue dots), and two small domains toward the carboxy terminus, the β' -component (β' -c) and the C-terminal component (Ct). The incomplete VtgC is phosvitinless (Pv-less) and also missing β' -c and Ct domains. See text for details. Redrawn from Hiramatsu, N., Matsubara, T., Fujita, T., Sullivan, C.V., Hara, A., 2006. Multiple piscine vitellogenins: Biomarkers of fish exposure to estrogenic endocrine disruptors in aquatic environments. *Marine Biology* 149, 35–47. (B) Model of vitellogenin lipid composition. The approximate average percentage of lipid in teleost Vtgs by weight is shown in the central white circle; surrounding colored wedges indicate that this is mainly phospholipid with smaller amounts of triglyceride, cholesterol and other lipids. Redrawn from Reading, B.J., Sullivan, C.V., 2011. Vitellogenesis in fishes. In: Ferrell, A.P. (Ed.), *Encyclopedia of Fish Physiology: From Genome to Environment. The Reproductive Organs and Processes. Reference Module in Life Sciences*, 2011 ed. Maryland Heights, MO: Elsevier., pp. 635–646. Available at: <https://doi.org/10.1016/B978-0-12-374553-8.00257-4>. (C) Models of the tertiary structure of the European sea bass (Sbs) VtgAb polypeptide mapped to the 3-dimensional structure of a lamprey Lv, whose crystalline structure has been resolved. The major structural features of the rotated monomer are shown color-coded to the linear VtgAb sequence (below). The location of the 85-residue motif binding the VtgAb receptor, termed the Vtg receptor-binding peptide (VRBP) is indicated, as is the large cavity where lipids are transported. Modeled after Finn (2007). Images from an unpublished study by Yilmaz, O. and Sullivan, C.V., with permission.

soluble in their lipid components. Vtgs are the primary source of amino acids for developing embryos and larvae, and they are particularly rich in alanine, which usually comprises ~10%–12% of total amino acids. Alanine is a crucial substrate of intermediary carbohydrate metabolism, especially embryonic gluconeogenesis (Finn and Fyhn, 2010).

Structure of Vitellogenin and Yolk Proteins

Complete forms of Vtg are made up of a linear series of five YP domains, as follows: Amino terminus (N)-lipovitellin heavy chain (LvH), phosvitin (Pv), lipovitellin light chain (LvL), β' -component (β' -c), and C-terminal peptide (Ct)-carboxy terminus-(C) (Fig. 3(A)). LvH is the major component, with an average mass of ~115 kDa, as compared to ~25 kDa for LvL (Lubzens *et al.*, 2017). Once cleaved from the parent Vtg, LvH and LvL associate to form lipovitellin (Lv), which includes 65%–100% of the Vtg by mass. Lv is comprised of amphipathic structures that form a basket lined with hydrophobic amino acid residues to accommodate lipids (Fig. 3(C)). Lv bears a Vtg receptor (Vtgr)-binding peptide (VRBP), which has the special shape and surface charge distribution required to bind to Vtgs on the oocyte surface (Fig. 3(C)). Lv is the main source of the polar lipid and amino acid nutrients that serve as catabolic energy substrates, or in anabolic synthesis of membranes or proteins, during early development. Phosvitin is

a small (~5–20 kDa) YP made up mainly of long stretches of extensively phosphorylated serine residues, empowering Pv to bind calcium, magnesium, zinc, and iron via ionic interactions. In freshwater fishes, these ions delivered to the yolk by Pv may be crucial as they are largely unavailable for uptake from the environment. However, some incomplete forms of Vtg lack a Pv domain altogether. The remaining small YPs (β' -c and Ct) together contain 14 highly conserved cysteine residues known to form disulfide linkages thought to be required for the complicated folding of Vtg polypeptides. The β' -c also contains a CGxC motif implicated in formation of interchain disulfide linkages during Vtg dimerization, which is required for receptor-mediated endocytosis of the Vtgs by the oocyte. When released from Vtg, β' -c forms an ~16 kDa YP, but, with some exceptions, Ct (~13 kDa) may be degraded shortly after cleavage. Various Lv-Pv conjugates (LvH-Pv, Pv-LvI, LvH-Pv-LvI) have been detected in the yolk of several species. See Finn (2007) for further details on Vtg-derived YPs.

Vitellogenin Classification and Nomenclature

Current nomenclature for classification of piscine Vtgs (Fig. 4(A)) is based upon them having arisen via three rounds of whole genome duplication (WGD) and some lineage-specific gene duplications (Finn and Kristoffersen, 2007), as follows. The ancestral

Fig. 4 Nomenclature and domain structure of fish vitellogenins. (A) Classification of multiple fish vitellogenins (Vtgs). VtgABCD, primitive chordate Vtg; VtgABII, chicken VtgII ortholog present in pre-teleost fishes; VtgABIII, chicken VtgIII ortholog present in pre-teleost fishes. Proto-VtgC, pre-teleostean VtgC containing a diminished phosvitin (Pv) domain; VtgC, chicken VtgI ortholog that contains Pv in pre-teleosts but is Pv-less in teleosts; VtgC?, indicates that the presence of VtgC in the taxon is unknown; VtgA, A-type teleostean Vtg; VtgAe, elopomorph VtgA; VtgAc, clupeomorph VtgA; VtgAo, ostariophysian VtgA; VtgAs, salmoniform VtgA. VtgAa, acanthopterygian ortholog of chicken VtgII; VtgAb, acanthopterygian ortholog of chicken VtgIII. Arabic numerals following a Vtg symbol identify duplicate forms of that Vtg. See text for details. (B) Major teleost taxa for which published information on Vtg structure is available are listed on the left side ordered by relationship. For each taxon, the corresponding linear subdomain structure of Vtg is shown for an example species of a representative order on the right side, with species images provided in the middle. Naming of yolk protein domains follows that shown in Fig. 3. Red arrows indicate special features of the respective Vtgs; see text for details. Portions redrawn from Reading, B.J., Sullivan, C.V., 2011. Vitellogenesis in fishes. In: Ferrell, A.P. (Ed.), Encyclopedia of Fish Physiology: From Genome to Environment. The Reproductive Organs and Processes. Reference Module in Life Sciences, 2011 ed. Maryland Heights, MO: Elsevier., pp. 635–646. Available at: <https://doi.org/10.1016/B978-0-12-374553-8.00257-4>.

chordate VtgABCD, present in silver lamprey, arose after the first round of WGD and gave rise to VtgAB and VtgCD after the second round. The VtgCD subsequently gave rise to VtgC, present in most major fish taxa, and to VtgD, which is extinct. Duplicate forms of VtgAB arose and are present in holocephalans (Chondrichthyes), lobe-finned fishes (Sarcopterygii, e.g. coelacanths), chondrosteans (e.g. sturgeons), holosteans (e.g. gars) and tetrapods, including amphibians and birds (Fig. 4(A)). Synteny analyses place these three types of pre-teleost Vtg in a highly conserved Vtg gene cluster (VGC) that has existed for over ~450 million years (Andersen *et al.*, 2017; and references therein) and show that they are orthologs of chicken (*Gallus gallus domesticus*) VtgI (VtgABI, also called VtgC), VtgII (VtgABII) and VtgIII (VtgABIII). An ancestral VtgAB gave rise to the A-type Vtg universally present in teleosts, and to a B-type Vtg that is extinct. Multiple or dual A-type Vtgs are present, for example, in Elopomorpha (e.g. anguillid eel VtgAe1–3) and Ostariophysi (e.g. ostariophysan VtgAo1 and VtgAo2 in Cypriniformes) (Fig. 4(B)). After a late round of WGD, VtgA gave rise to two paralogs present in higher teleosts (Acanthomorpha) as VtgAa and VtgAb (Finn and Kristoffersen, 2007). Acanthomorph VtgC, VtgAa and VtgAb are also orthologs of chicken VtgI, VtgII and VtgIII, respectively.

The VtgC of teleost fishes is ‘incomplete’, without Pv, β' -c and Ct domains, consisting only of Lv (also termed ‘phosvitinless’ Vtg). The C-type Vtgs of the holocephalan elephant shark (*Callorhynchus milii*), a chimera (class Chondrichthys), and the West Indian coelacanth (*Latimeria chalumnae*), a sarcopterygian, both have shortened Pv domains and are referred to here as Proto-VtgCs (Fig. 4(A)). Pre-teleostean C-type Vtgs with complete Pv domains also exist, such as the tandem VtgC1 and VtgC12 in the spotted gar (*Lepisosteus oculatus*), a holostean. Other partial Vtg gene deletions are evident among teleosts (Fig. 4(B)). As examples, the ostariophysan VtgAo1 seen in zebrafish, *Danio rerio* (Cypriniformes) contains Pv but has lost its β' -C and Ct domains, and in the Atlantic salmon, *Salmo salar* (Salmoniformes), the VtgAsb has been reduced to just its LvH domain (Fig. 4(B)). An extreme example of Vtg duplication and deletion occurs in the rainbow trout, *Oncorhynchus mykiss* (Salmoniformes), where the locus of the gene encoding VtgAsa is duplicated in tandem 20 times and the gene encoding the corresponding VtgAsb has been deleted.

Regulation of Vitellogenesis

Major environmental cues regulating vitellogenesis include seasonal changes in water temperature and daylength, but almost anything predictive of successful reproduction can serve as a cue (Fig. 5). Examples include rainy weather (e.g. ‘monsoon season’), which may flood preferred spawning areas, and the presence of conspecific males. The converse is also applicable, as the perceived absence of positive cues is inhibitory. An example in some farmed fishes that spawn every few days is the response to removal of males from the tank, which causes females to cease reproductive processes, terminate vitellogenesis, and undergo massive pre-ovulatory atresia (Fig. 1). Internal cues signaling adequate nutritional status or fat reserves also influence

Fig. 5 Model for regulation of vitellogenesis in teleost fish via the brain-pituitary-gonad (BPG) axis. Environmental cues pictured at the top indicate (from left to right) water temperature, daylength, rainy weather, conspecific males and/or females, and xenoestrogens in the environment. Xenoestrogens are shown impacting the BPG axis at several levels. Fsh, follicle stimulating hormone; GnRh, gonadotropin-releasing hormone; Lh, luteinizing hormone; E2, 17 β -estradiol. See text for details.

vitellogenesis and may be especially important where seasonal cues are lacking. Information imparted by received cues is integrated in the brain, ultimately influencing the activity of neurons emanating from the preoptic area that course to the anterior lobe of the pituitary gland and terminate on the gonadotrophic cells. These neurons secrete a short peptide called gonadotropin releasing-hormone (Gnrh) that induces the gonadotrophs to synthesize and secrete gonadotropins (Fig. 5). Fish possess two gonadotropins similar to those in higher vertebrates, follicle stimulating hormone (Fsh) and luteinizing hormone (Lh). Depending on species and reproductive status, one or both of these gonadotropins acts on responsive ovarian follicle cells to stimulate their synthesis and secretion of the estrogen, estradiol-17 β (E2). Circulating E2 then induces hepatocytes in the liver to synthesize and secrete Vtgs. E2 also feeds back to act on the brain and pituitary gland, providing homeostatic control of vitellogenesis and later maturational processes. Xenoestrogens present in the environment can 'short-circuit' the brain-pituitary-gonad axis and act directly on the liver to induce abnormal vitellogenesis in male and juvenile fish, sometimes resulting in the appearance of 'intersex' males bearing previtellogenic oocytes in their testes, and in reproductive failure (Fig. 5). Vitellogenesis is highly responsive to synthetic and natural estrogens, and fish Vtgs have been globally adopted as biomarkers of the presence of estrogenic chemical contaminants in aquatic environments, which is indicated by elevated Vtg levels in the blood or tissues of male and/or and juvenile fish (Dang, 2016; Adeel *et al.*, 2017).

Vitellogenin Synthesis and Secretion

Induction of vitellogenesis depends on interaction of estrogen with the classical nuclear estrogen receptor (Esr) (Babin *et al.*, 2007) (Fig. 6), of which there are two subtypes in teleosts, Esr α and Esr β . In most species examined, Esr α is more closely linked to activation of vitellogenesis but both Esr subtypes play a role in certain species. The form of Esr residing in the cell membrane that can rapidly activate transcription via non-genomic pathways is not involved in inducing vitellogenesis. Estrogen enters liver cells and binds to cytosolic Esr, inducing conformational changes that enable it to recruit several co-regulatory proteins required for activation of Vtg gene transcription. The occupied Esr is translocated to the cell nucleus where it dimerizes with another Esr, becoming an activated transcription factor that binds to specific palindromic DNA sequence motifs, named estrogen response elements (EREs), that are present in the promoter region of genes encoding Vtgs (Fig. 6). The bound hormone-receptor complex and interacting co-regulators alter the structure of chromatin, the complex of DNA and proteins forming the chromosomes, and

Fig. 6 Hepatic vitellogenesis regulated by estradiol. Estradiol (E2) passes from the bloodstream into the liver cell (hepatocyte) cytoplasm where it binds to estrogen receptors. The occupied receptors undergo conformational changes and are translocated to the nucleus where they dimerize and bind to estrogen response elements (EREs) in DNA sequences in the promoter region upstream of the target vitellogenin (Vtg) genes. Transcription of Vtg genes is initiated and resulting mRNAs transit to the rough endoplasmic reticulum where they provide a template for translation of Vtg polypeptides on the ribosomes. The nascent Vtg polypeptides are loaded with lipid and packed into transport vesicles for travel to the Golgi body where final post-translational modifications (glycosylation, phosphorylation) and dimerization are accomplished. Secretory vesicles carrying newly synthesized Vtg dimers bud off from the Golgi body and fuse with the peripheral cell membrane to discharge their contents. See text for details.

recruit onsite the machinery required to activate gene transcription (e.g. RNA polymerase II), leading to an increase in mRNA transcripts and to stabilization of the nascent mRNA. Estrogen-Esr complexes can also be tethered via protein-protein interactions to transcription factor complexes targeting binding sites distinct from EREs, and several transcription factors other than Esrs have binding sites located in the presumed promotor regions of genes encoding teleost Vtgs (Lubzens *et al.*, 2017). Ribosomes on the rough endoplasmic reticulum (RER) translate the mRNAs encoding Vtgs into their respective polypeptides (Fig. 6, inset) which are trimmed of their signal peptide, loaded with lipid by Mtp, partially folded and possibly partially glycosylated within the RER before being loaded into endosomes for transport to the Golgi apparatus. The Vtg polypeptides are then glycosylated, phosphorylated on their Pv domains, folded into final configuration, and dimerized. Once all post-translational modifications are complete, the finished Vtgs present in cisternae of the *trans*-Golgi are loaded into secretory vesicles that fuse with the cell membrane to release them into the circulation for transit to the ovary.

Vitellogenin Uptake and Processing Into Yolk Proteins

Vitellogenins exit fenestrated (porous) capillaries in the follicle theca and pass through the basement membrane and inter-cellular spaces among granulosa cells to reach the oocyte surface, where they bind to specific Vtg receptors (Vtgrs) (Fig. 7). Occupied Vtgrs cluster into clathrin-coated pits that invaginate and are endocytosed, becoming endocytotic vesicles from which the clathrin coat is later removed and recycled (not shown). Endocytosed Vtg dissociates from the Vtgrs due to slight vesicle acidification and the Vtgrs are recycled to the oocyte surface. The vesicles, now called endosomes, fuse with lysosomes containing inactive cathepsin D (CatD) proenzymes to form multivesicular bodies (MVBs). Vacuolar ATPases (i.e., proton pumps) located in the surface membrane further acidify the lumen of the MVBs and the decreased pH (~ 6.0) activates CatD, which cleaves Vtg at specific recognition sites into its product YPs (LvH, LvL, Pv, β -c, and Ct) (Fig. 7) (Reading *et al.*, 2009). In some cases, cleavage is imperfect and the Pv domain remains covalently linked to LvH, LvL, or both, generating LvH-Pv, Pv-LvL, or LvH-Pv-LvL conjugates, respectively. Smaller proteolytic fragments of LvH or other YPs may also be present and result from imperfect or nonspecific Vtg cleavage. LvH associates with LvL to form Lv dimers that, along with the remaining dimeric YPs, are stored in yolk granules, globules or platelets, or as fluid yolk.

It was recently discovered that there are two forms of Vtg receptor in acanthomorph fishes. A novel receptor termed Lrp13 that preferentially binds VtgAa was discovered in the white perch, *Morone americana* (Perciformes), where the 'classical' Vtgr

Fig. 7 Model of oocyte growth during vitellogenesis in an acanthomorph teleost. Complete forms of A-type vitellogenin (VtgAa and VtgAb) bind to the vitellogenin receptor (Vtgr) and are taken up into oocytes via clathrin-mediated endocytosis where they are cleaved by cathepsin D into product yolk proteins that are stored in the yolk vesicles. The C-type Vtg (VtgC) may enter the oocyte by other means. MVB, Multivesicular body. See text for details. Portions redrawn from Hiramatsu, N., Cheek, A.O., Sullivan, C.V., Matsubara, T., Hara, A., 2005. Vitellogenesis and endocrine disruption. In: Mommsen, T.P., Moon, T.W. (Eds.), *Biochemistry and Molecular Biology of Fishes*, vol. 6. Amsterdam: Elsevier, pp. 431–471.

preferentially binds VtgAb (Hiramatsu *et al.*, 2015). In the cutthroat trout, *Oncorhynchus clarki* (Salmoniformes), a paracanthopterygian fish, another version of Lrp13 bound both A-type Vtgs (VtgAsa and VtgAsb), as did the classical Vtgr. These findings suggest that a system of dual Vtg receptors with distinct affinities for the two forms of Vtg (VtgAa and VtgAb) evolved in acanthopterygian fishes, which would provide the capability to target them into different compartments in growing oocytes, where could be separately stored and independently mobilized for proteolysis during oocyte maturation (Reading and Sullivan, 2011; see below). Accordingly, the simple model for oocyte growth in acanthomorph fishes shown in Fig. 7 can be duplicated showing a different receptor for each form of A-type Vtg and possibly separate storage compartments (yolk vesicles) within the ooplasm. While proteins that bind to VtgC have been detected in several species, no specific VtgC receptor has been definitively identified and several lines of evidence suggest that VtgC may lack an oocyte receptor and enter oocytes via common endocytosis or in association with other proteins, possibly including Vtgs. See Reading *et al.* (2017) for further details on these Vtg receptors.

Cytoplasmic Maturation and Yolk Protein Proteolysis

Fully-grown, postvitellogenic follicles undergo final maturation, including resumption of meiosis and cytoplasmic maturation, which involves fusion and dissolution of the yolk granules, coalescence of the lipid droplets, ooplasm clarification, and oocyte hydration with an increase in oocyte size due to the uptake of water (Fig. 8, see also Fig. 1). In higher (acanthomorph) teleosts, a 'secondary proteolysis' of the YPs occurs at this time. The contents of the yolk vesicles are further acidified via activity of vacuolar ATPase (V-ATPase) and chloride channels on their outer membranes, activating cathepsins B or L (CatB/L), which are co-localized with YPs in the yolk vesicle during oocyte growth. These cathepsins accomplish proteolytic degradation of the YPs, generating a large pool of peptides and free amino acids (FAA). The FAA along with other osmolytes, including Pv-derived phosphate, ammonium (NH_4^+) from FAA metabolism, and potassium and chloride transported into the oocyte via the actions of Na^+ , K^+ -ATPase and pendrin, respectively, increase the osmotic pressure of the ooplasm, causing water to flow into the oocyte through aquaporin channels transiently expressed in the oocyte membrane (Fig. 8). The net results are hydration of the oocyte, adjusting its density to provide for proper egg buoyancy, provision of a pool of diffusible FAA nutrients, which are the preferred energy substrate of early embryos, and retention of remaining polypeptides and Lv fragments as nutrients for late-stage embryos and larvae, which have developed the

Fig. 8 Model of oocyte maturation and utilization of yolk proteins in European sea bass, *Dicentrarchus labrax*. Yolk proteins present in the yolk vesicles are cleaved into smaller polypeptides and free amino acids (FAA) by cathepsin (Cat) B and/or CatL activated by further acidification of the yolk vesicles mediated by V-ATPase and associated chloride (Cl^-) channels. The resulting pools of FAA and phosphate (P), together with potassium (K^+) and Cl^- ions pumped into the oocyte by sodium-potassium-ATPase (Na^+/K^+ -ATPase) and ammonium (NH_4^+) ions arising from FAA metabolism, increase osmotic pressure, leading to oocyte hydration. Hydration is mediated by the transient opening of water channels, termed aquaporins, embedded in the cell membrane, which allow water to flow into the ooplasm, causing the oocyte to swell in volume and ultimately resulting in the acquisition of proper egg buoyancy. The FAA are diffusible nutrients selectively utilized by early stage embryos. Late stage embryos and larvae are increasingly dependent on the larger polypeptides and lipoproteins for nutrition. Portions redrawn from Finn, R.N., Fyhn, H.J., 2010. Requirement for amino acids in ontogeny of fish. *Aquaculture Research* 41, 684–716.

machinery to process such macromolecules (e.g. the yolk syncytium). Aside from gas exchange, the egg is largely a closed system during early stages of embryogenesis, and the water taken up during final maturation is required for embryo metabolism, dilution of metabolic wastes (e.g. NH_4^+), and provision of adequate space for further development (Finn and Fyhn, 2010).

The model of oocyte maturation shown in Fig. 8 depicts the process as described for European sea bass (Yilmaz *et al.*, 2016) in which the Lvs derived from all three forms of Vtg undergo only limited proteolysis, with large portions of LvH and most of LvL remaining intact. Eggs of this species and other Moronidae family members possess a large oil droplet filled with low-density oil (e.g. wax esters) that provides for proper egg buoyancy. The requirement of oocyte hydration to achieve neutral buoyancy is, therefore, limited and the oocytes increase in volume only 2–3 fold during final maturation. In contrast, for oocytes of species such as barfin flounder (*Verasper moseri*), Atlantic halibut (*Hippoglossus hippoglossus*) and haddock (*Melanogrammus aeglefinus*), that spawn pelagic eggs lacking large oil droplets in seawater, the requirement for oocyte hydration is greater and the oocytes increase in volume 4–6 fold during final maturation (Yilmaz *et al.*, 2015). In these species, the YPs derived from VtgAa are almost entirely cleaved into FAAs, whereas proteolysis of the major YP derived from VtgAb (i.e., LvHAb) is quite limited. It is thought that the system of distinct receptors for the two forms of A-type Vtg in these species may allow them to be targeted into different compartments in the oocyte where maturational proteolysis of their product YPs could be separately regulated. Typically, the YPs derived from VtgC undergo very limited maturational proteolysis. It is possible that, in the absence of a VtgC receptor, these YPs may not be targeted into yolk vesicles or be subject to the proteolytic processes discussed above.

Novel Functions of Vitellogenins

In addition to their fundamental functions as primary precursors of YPs and as transporters of lipids and other nutritional resources into the egg yolk, teleost Vtgs have become objects of curiosity for their novel, non-nutritive functions. It is increasingly evident that Vtg is an immunocompetent factor capable of protecting the host against attack by microbes including bacteria and viruses (Sun and Zhang, 2015; Li and Zhang, 2017). Both serum Vtg and its product YPs, Lv and Pv, are immunologically active via their ability to recognize and bind to pathogen-associated molecular patterns (PAMPs). These properties of multivalent pattern recognition receptors were associated with the ability of Lv and Pv to bind Gram-positive and -negative bacteria through recognition of their conserved lipopolysaccharide, peptidoglycan, lipoteichoic acid and glucan components. Pv was shown to be an effector molecule capable of killing bacteria directly via cell lysis, while Lv was shown to act as an opsonin, facilitating phagocytosis of bacteria by macrophages. Serum Vtg has been additionally reported to bind and neutralize infectious pancreatic necrosis virus. The antimicrobial properties of certain conserved domains present in zebrafish VtgAo2 were verified by producing them as recombinant proteins and testing their bioactivity. These domains encompassed the carboxy-terminal third of LvH, most of LvL, and all of β' -c. All three recombinant domains functioned as pattern-recognition receptors, binding both Gram-positive and -negative bacteria and their isolated signature PAMPs, and those including portions of LvH or LvL also functioned as opsonins, promoting phagocytosis of *Escherichia coli* (–) and *Staphylococcus aureus* (+) by carp, *Cyprinus carpio*, macrophages. Native Lv was associated with immune defense of rosy barb, *Pethia conchonius*, embryos and larvae and Pv was shown to possess antimicrobial activity in zebrafish embryos and larvae. The protective immune functions of Vtg-derived YPs may extend through oocyte maturation and ovulation to embryonic and larval development, when the YPs have been degraded into smaller polypeptides. For example, three small polypeptides derived from the C-terminal 55 residues of a zebrafish Pv have been shown to have individual and enhanced collective activity against growth of *S. aureus* (+) and *Aeromonas hydrophila* (–) bacteria and, thus, may have protective activity in developing embryos. Vtg may also contribute to immune priming by carrying immunological memory from mother to offspring, as it does in insects.

Vitellogenins are also known to have antioxidant activity and the capability to suppress free-radical reactions in fish oocytes and to protect the host from oxidative stress. It has been demonstrated that hen egg yolk Pv exhibits strong antioxidant activity owing to its high serine and phosphorus content, which makes it a particularly strong iron-chelating agent. It has also been shown that zebrafish recombinant Pv (rPv) is an antioxidant capable of protecting against radical-mediated oxidation of cellular biomolecules (Sun and Zhang, 2015). Several studies have demonstrated that Vtg regulates honey bee aging by boosting antioxidant balance of the body via its antioxidative properties, thus slowing down physiological aging and inhibiting inflammation by reducing oxidative stress. It is intriguing to speculate that Vtg may have similar activities in fishes.

Future Directions and Perspectives on Vitellogenesis

The past 20 years have seen great strides in our understanding of vitellogenesis in fishes. However, much remains to be learned. Our first glimpses into molecular mechanisms for control of Vtg gene transcription in zebrafish have revealed much complexity and the likelihood that Vtg gene promoters are sites of considerable crosstalk between numerous types of transcription factors, just as physiology studies revealed that several hormones besides estrogen modulate vitellogenesis. Almost nothing is known about the ways in which different types of Vtg are regulated by these processes. This will be a rich and rewarding area for future research.

It is now understood that multiplicity of Vtgs is the norm in fishes and that parallel multiplicity of Vtg receptors may exist, particularly in higher (acanthomorph) teleosts. These fishes exhibit different ratios of abundance of VtgAa, VtgAb and VtgC in their bloodstream and these ratios change during the reproductive cycle and differ between blood plasma and oocytes. These differences

likely reflect variation in hepatic secretion of the different types of Vtg, and also differences in their rates of sequestration by oocytes via receptor-mediated endocytosis, with both processes modulated to optimize the mixture of Vtg-specific YP products deposited in growing oocytes. These hypotheses remain to be experimentally verified.

Maturation proteolysis of YPs in acanthomorph fishes spawning pelagic eggs in seawater appears to be regulated to optimize oocyte hydration, egg buoyancy and delivery of the preferred types of nutrients to early embryos and late stage larvae. In such species whose eggs lack prominent oil droplets, VtgAa is neofunctionalized for susceptibility proteolysis, and it is hypothesized that the newly discovered receptor that preferentially binds VtgAa (Lp13) may deliver it into a special compartment where it is fated for digestion during maturation, whereas the VtgAb is targeted by a different receptor (Vtgr) to a different compartment. The identity and functional details of these compartments need resolution.

The basic biology of the C-type Vtg is poorly understood. In higher teleosts, VtgC usually escapes significant proteolysis during final maturation, but it is uncertain how this is achieved. There is presently no definitive evidence that VtgC binds to a specific receptor that delivers it into a 'protected' compartment, nor is there evidence that VtgC even enters yolk vesicles where it would be subject to proteolysis by CatB/L during final maturation. It is known that dephosphorylated Vtg cannot bind to Vtg receptor(s), and VtgC, lacking a Pv domain, is constitutively 'dephosphorylated'. VtgC also lacks the vWfd domain (β' -c, Ct) thought to be important for dimerization and perhaps cell adhesion associated with receptor mediated endocytosis. In short, the molecular biology of VtgC is a mystery and 'low hanging fruit' for a scientist wishing to make an important contribution to the study of fish vitellogenesis.

The formation of the avian egg relies on two distinct anatomical structures, the ovary and the oviduct, as part of the female reproductive tract. Initially, two ovaries are present during early embryogenesis but the right ovary will be progressively resorbed and only the left oviduct will finally develop at sexual maturity of the female bird. The ovary synthesizes sex steroids and is where the gametogenesis, the vitellogenesis and the inner layer of the vitelline membrane occur, whereas the outer layer of the vitelline membrane, the egg white, the eggshell membranes and the eggshell are successively deposited in the various segments of the oviduct around the mature yolk follicle, immediately after its ovulation in the infundibulum, the more proximal part of the oviduct (Fig. 1). In the domestic fowl (*Gallus gallus*), yolk accumulation into growing follicles is a 10–12 day process taking place in the ovary, where some oocytes are selected at daily intervals, among the several thousand oocytes present in the ovary at hatch. Sexual maturity coincides with the hormonal stimulation of hepatic synthesis of pre-existing proteins or synthesis of new proteins and lipids that are secreted in the blood as egg yolk precursors (very-low density lipoproteins, vitellogenins, etc.). Egg yolk precursors are then conveyed to the ovarian follicles, which each consists of an oocyte surrounded by layers of supportive tissues, the theca externa and the theca interna, containing embedded capillaries which are separated from the granulosa layer by a thick basal lamina (Fig. 2; Perry and Gilbert, 1979). Yolk precursors are progressively internalized in growing follicles by receptor-mediated endocytosis and further processed into functional proteins by endogenous yolk proteases. After oviposition and during incubation, yolk nutrients including proteins and lipids are subsequently assimilated by the embryo, via the yolk sac, which is a highly vascularized and specialized extra-embryonic tissue supporting the embryo growth during the entire phase of embryogenesis. It must be emphasized that most of the literature available on cellular and molecular mechanisms regulating vitellogenesis and follicle growth, are derived from domestic species (*Gallus gallus*, *Coturnix japonica*, *Meleagris gallopavo*).

Chronologia and Regulation of Vitellogenesis

Follicular Growth

The viability and the growth of follicles is controlled by endocrine factors (e.g., gonadotropins), paracrine and autocrine factors produced within the ovary, and neurochemical/neurohumoral factors locally expressed by the nervous system (Johnson and Woods, 2007). The process of follicle growth, from the primordial follicle to ovulation, is divided into three main phases (Fig. 3): early, slow and rapid growth phases. The early growth of primary follicles is assumed to take months to years. In contrast, the slow growth of prehierarchal (or previtellogenic) follicles lasts weeks to months. During this latter phase, follicles initially incorporate “white” yolk and can be referred to small white follicles (<2 mm) and large white follicles (2–5 mm). These latter then become small yellow follicles (5–9 mm) concomitantly with the uptake of “yellow” yolk. In comparison with “yellow” yolk, “white” yolk is characterized by a higher protein to lipid ratio and contains only 10–13% solid material (Gilbert, 1979). The rapid growth of preovulatory follicles is featured by the transfer of large amounts of “yellow” yolk and ends 2–3 h before ovulation. The duration of this phase varies according to avian species: 6 and 11 days in the domestic hen and barn owl, approximately 12 days in the Canada goose (*Branta canadensis*), up to 16 days in some penguins, 15–17 days in the Brown kiwi (*Apteryx mantelli*), but only 5–7 days in the Ring-necked dove (*Streptopelia capicola*) and Japanese quail (*Coturnix japonica*) (Gilbert, 1979). In domestic hens, the ovary generally contains five preovulatory follicles with increasing size (follicular hierarchy), named F1 to F5, F1 being the largest follicle.

Fig. 3 Follicular growth in the domestic fowl (*Gallus gallus*). Drawn based on a picture from Johnson, A.L., Woods, D.C., 2007. Ovarian dynamics and follicle development. In: Jamieson B.G.M. (Ed.), *Reproductive Biology and Phylogeny of Birds (Part A)*, pp 243–277. Science Publishers.

Synthesis of Yolk Lipids and Proteins

Yolk lipids and protein precursors are synthesized in the liver and then secreted into the blood stream to reach the ovary where they are transferred into the oocyte. The synthesis of these yolk compounds, under the control of estrogen, is strongly induced at sexual maturity (about 16 weeks of age in domestic laying strains). A 15- and 20-fold increase in hepatic lipogenesis and lipemia can indeed be observed in mature hens compared with immature hens. Yolk lipids are produced and transported to the ovary as very low-density lipoproteins (VLDLs). VLDLs have a standard structure consisting of a core composed of triglycerides and cholesterol esters and surrounded by a surface layer of phospholipids, cholesterol and apoproteins (mainly apolipoprotein B and apovitellenin-1, also known as apolipoprotein VLDL- II) (Fig. 4). VLDL levels in blood plasma are lower than 1 g/L in immature hens and increase up to 10–20 g/L in mature hens. In mammals, VLDL undergoes a rapid lipolysis into low-density lipoprotein (LDL) by a lipoprotein lipase after being secreted by the liver; however, in hens, VLDLs are stable and remain under their native form until they are transferred into the follicle. This stability to lipolysis is likely to involve apovitellenin-1, a very potent lipase inhibitor (see [Section Lipoproteins](#)). Vitellogenins (VTG), the main protein precursors of yolk (see [Section Vitellogenins](#)), is not present in immature hens and its synthesis is stimulated by estrogen at sexual maturity. The gene transcription is induced by the association of estrogen with its nuclear receptor and subsequent interaction of this hormone-receptor complex with a specific palindromic DNA sequence (estrogen responsive element) located within the gene promoter region. An important fraction of egg yolk protein is constituted by maternal immunoglobulins IgY (mammalian equivalent of IgG), which provides protection against pathogens to the developing embryo and to newly hatched chicks. It is noteworthy that, unlike most yolk proteins, IgY is not synthesized by the liver but by plasma cells which themselves are derived from B lymphocytes, following exposure to pathogens.

Yolk Transfer into Growing Oocyte

Yolk precursors are transported to the follicular wall via the blood stream and are released near the basal lamina (Fig. 2) through highly fenestrated capillaries (Gilbert, 1979; Etches, 1996). The presence of gaps within the endothelial wall allows VLDL and VTG to exit the blood stream and to diffuse toward granulosa cell layer and the oocyte.

During the early growth of prehierarchal follicles, white yolk may cross the granulosa cell layer either by transcytosis or by a paracellular transport. Granulosa cells are tightly connected to each other's by tight junctions, which restrict the paracellular transport of yolk at this stage (Fig. 2). Occludin, a protein involved in tight junctions, is likely to have a major role in the regulation of yolk transport and follicular growth. Its expression is regulated by the stimulatory effects of Follicular Stimulating Hormone (FSH) and activin (Transforming Growth Factor β superfamily member). The level of occludin progressively decreases during follicle growth, thus allowing greater amounts of yolk (including the lipid-rich yellow yolk) to cross the granulosa cell layer toward the oocyte. The yellow color gained by the 5–9 mm prehierarchal follicles (small yellow follicles) results, at least in part, from this mechanism (Johnson and Woods, 2007).

VLDL and VTG are internalized into oocytes by receptor-mediated endocytosis. These two components bind to LR8 receptor present at high levels in oocyte plasma membrane (Nimph and Schneider, 1998). The binding of VLDL and VTG to the receptor and their internalization are mediated by apolipoprotein B and lipovitellin (a vitellogenin-derived product, see [Section Vitellogenins](#)), respectively. The association of VLDL and VTG to LR8 in the oocyte plasma membrane leads to the formation of a vesicle internalized by endocytosis. The vesicle internalization in the oocyte is facilitated by the presence of endophilin III, a member of a protein family (endophilins) involved in clathrin-mediated endocytosis and recycling. LR8 has the ability to bind not only VLDL and VTG, but also other moderate-abundant components. For instance, α 2-macroglobulin (α 2M), a protein able to bind covalently to and neutralize serum proteases in mammals, can also bind LR8. By this mechanism, α 2M might indirectly promote the transfer of blood proteases into the oocyte. A number of yolk proteins can also enter the oocyte either after interaction with LR8 ligands (especially VTG and VLDL) as it is the case for riboflavin-binding protein, which is able to associate with VTG, or possibly by passive internalization during the formation of vesicles. The crucial role of LR8 in the internalization of yolk components is

Fig. 4 Schematic representation of a very low-density lipoprotein (VLDL).

demonstrated in vivo in 'restricted ovulator' (R/O) hens, which carries a point mutation at the *Lr8* locus leading to functional inactivation of LR8 (Bujo *et al.*, 1995). R/O hens are indeed not capable of laying eggs due to the inability of oocytes to enter the rapid growth phase. LR8 is initially located within the oocyte cytoplasm in slow growing follicles, and the rapid yolk intake occurs only following its redistribution to the oocyte plasma membrane (Johnson and Woods, 2007). A recent proteomic study performed on small white yolk follicles demonstrated that the receptor is present in the cytoplasmic compartment while VTGs are mostly detected within the follicular wall and ovarian stromal cells, but not in the cytoplasm (Nepomuceno *et al.*, 2015).

Immunoglobulins IgY are transferred from the blood to the oocyte by an immunoglobulin receptor in the oocyte membrane called FcRY and belonging to the mannose receptor family. Up to 100 mg of IgY can be found in the egg yolk of one egg, which represents a total of 17–35 g of IgY transferred in egg yolk per hen, per year.

Egg Yolk Proteins

Egg yolk biological function in avian reproduction is to provide essential nutrients and bioactive components for the developing embryo. In this respect, egg yolk consists of approximately 48% water, 34% lipids, 16% proteins, 0.5% carbohydrates and 1.5% ash. It is also a rich source of vitamins (A, D, E, B1, B2, B3, B5, B6, B8, B12, with no vitamin C), minerals (phosphorus, calcium and potassium) but also trace elements (zinc, copper etc.). Yolk is a complex milieu containing 68% low-density lipoproteins, which structure relies on a core of triglycerides, and cholesteryl esters, surrounded by a monolayer of phospholipids and cholesterol in which apoproteins are embedded (Fig. 4), 16% high-density lipoproteins (HDLs), 10% livetins and other soluble proteins, and 4% phosvitins. These components are distributed between non-soluble protein aggregates (granules) and a clear yellow fluid (plasma) (Anton and Gandemer, 1997). Granules (19–23% of dry matter) account for about 50% of yolk proteins and 7% of yolk lipids, and include HDLs (70%) and phosvitins (16%). The yolk plasma (77–81% of dry matter) is composed of 85% LDLs (with apolipoprotein B and apovitellenin-1 as the major components) and 15% soluble proteins (serum albumin, immunoglobulins and ovalbumin...). It concentrates yolk lipids (and nearly all carotenoids) and 50% of yolk proteins.

Two proteomic approaches performed in parallel on yolks collected from freshly laid eggs revealed a total of 216 distinct proteins distributed between granules and the plasma fraction (Mann and Mann, 2008). The protein profile and their relative abundance are presented Fig. 5(a) and (b). In egg yolk, major proteins encompass serum albumin (Gene ID: 396197), 12kDa serum protein also known as "predicted beta-microseminoprotein-like" (Gene ID: 100858647), apovitellenin-1 (Gene ID:396476), vitellogenins 1, 2, and 3 (Gene ID: 424547, 424533 and 424534, respectively), ovalbumin (Gene ID: 396058), immunoglobulins Y (Gene ID: 416928), apolipoprotein B (Gene ID: 396535), similar to avidin (Gene ID: 426220), ovotransferrin (Gene ID: 396241), transthyretin (Gene ID: 396277), cystatin (Gene ID: 396497), similar to α 2-macroglobulin-like (Gene ID: 100858010) and apolipoprotein A-I (Gene ID: 396536) (Fig. 5). The next paragraphs will give an overview of the biological activities of some of these major proteins.

Lipoproteins

The most abundant proteins recovered in the yolk (essentially in granular fraction of the yolk) are apolipoprotein B and apovitellenin-1. The 520kDa apolipoprotein B functions as a recognition signal for the cellular binding and internalization of the very low-density lipoprotein (VLDL) particles from the blood by the chicken oocyte receptor, which is present at high levels in the oocyte membrane (Bujo *et al.*, 1997). Its role is to store and deliver lipid nutrients to the developing embryo. Apovitellenin is a 14kDa-homodimer integrated in the very low density lipoprotein (VLDL) of egg-laying females. It exhibits a potent lipase inhibiting activity, preventing the loss of triglycerides from VLDL, on their way from the liver to the growing oocytes. Its expression by the liver is 40-fold increased in hens at sexual maturity (Bourin *et al.*, 2012). Three other apoproteins of moderate or low abundance have also been detected by proteomic approaches: apolipoprotein A-I, apolipoprotein H and apolipoprotein C-III (Fig. 5(b); Mann and Mann, 2008).

Vitellogenins

Vitellogenin-1 and vitellogenin-2 (the most abundant of the three vitellogenins) are two high molecular weight glycoproteins (200kDa) containing 4 domains, lipovitellin-1, lipovitellin-2, phosvitin and a peptide of 40 amino-acids called YGP40, which are specifically released after intraoocytic proteolytic processing by cathepsin D, an endogenous aspartic protease (Retzek *et al.*, 1992). The genes coding these two proteins are overexpressed by more than 40 fold and 30 fold, respectively, in the liver of sexually mature hens (Bourin *et al.*, 2012). In contrast, vitellogenin 3 is a smaller glycoprotein (37kDa) lacking lipovitellins and YGP40 domains but containing phosvitin. Vitellogenin-derived phosvitins sequester and store calcium, iron and other cations from the bloodstream to relocate them to the yolk, to further provide minerals and trace elements for the developing embryo. Similarly, lipovitellins are lipid-bound proteins, which function is to fulfill lipid requirements for embryo growth.

Immunoglobulins

Immunoglobulin Y is the dominant immunoglobulin in serum and egg yolk, in birds. Compared to immunoglobulin G, its mammalian counterpart, its characteristics and functions are similar but it displays distinct structural differences containing three constant heavy domains (as opposed to two in mammals) and an absence of the hinge region between light and heavy chains, this

Fig. 5 Egg yolk proteins. (a) Protein profile of egg yolk (SDS-PAGE followed by Coomassie blue staining (Personal data)). (b) Relative abundance of egg yolk proteins: proteins of high abundance ($1650 < \text{emPAI} < 6840$), abundant proteins ($100 < \text{emPAI} < 400$), proteins of moderate abundance ($10 < \text{emPAI} < 100$), proteins of low abundance ($1 < \text{emPAI} < 10$), proteins of very low abundance ($\text{emPAI} < 1$). Adapted from Mann, K., Mann, M., 2008. The chicken egg yolk plasma and granule proteomes. *Proteomics* 8 (1), 178–191.

latter feature being associated with reduced flexibility compared to the immunoglobulin G. Immunoglobulin Y was initially associated with the gamma-livetin fraction of the yolk. Its concentration in egg yolk remains very variable from one individual to another and can reach up to 7–10mg/mL. These immunoglobulins are specific to the microbes encountered by the hen during its lifespan, and are captured from the bloodstream to be incorporated in ovarian growing follicles. These maternal

immunoglobulins ensure the protection of the embryo during incubation but more surely to the chick, after abdominal resorption of the residual yolk sac occurring just before hatching.

Vitamin and Iron-Binding Proteins

Yolk contains significant amounts of vitamin- and cofactor- binding proteins. Riboflavin-binding protein expression in the liver is stimulated by 68 fold in hens at sexual maturity (Bourin *et al.*, 2012). This highly abundant protein is presumed to provide riboflavin to the developing embryo since a lack of this protein in egg yolk is lethal for the 10-day old embryo. Some vitamin-binding proteins of moderate to low abundance have been detected in the yolk: "Similar to avidin," a biotin (vitamin B8)-chelating protein, plasma retinol (vitamin A)-binding protein and vitamin-D binding protein and two presumed cobalamin (vitamin B12)-binding proteins (Mann and Mann, 2008; Farinazzo *et al.*, 2009). All these vitamins are essential for the proper growth of the embryo.

Low Abundant Proteins

Besides, many proteins with low or very low abundance have been detected (Fig. 5(b)) (Mann and Mann, 2008) but their biological significance in the yolk remains uncertain. Indeed, most of these proteins are basically present in sera of pullets like hemostatic and fibrinolytic factors, carrier proteins and immune effectors (thrombin, alpha 1-antitrypsin, fibrinogen alpha chain, similar to complement C8, coagulation factor X, complement C3, similar to prekallikrein, similar to plasminogen, heparin cofactor II, similar to complement component C5, similar to angiotensinogen, similar to antithrombin, similar to plasma protease C1 inhibitor etc.) and no specific stimulation of their expression in hens at sexual maturity has been reported (Bourin *et al.*, 2012). The ongoing hypothesis is that they may be incorporated passively during vitellogenesis together with egg yolk specific proteins such as apovitellenin-1, apolipoprotein B, riboflavin-binding protein etc., which in contrast to these minor proteins, are specifically expressed or over-expressed in hens at sexual maturity (Bourin *et al.*, 2012). In such a context and with regards to their very low abundance in egg yolk, their active role during embryonic development remains controversial.

Evolution of Yolk Proteins During Embryogenesis

A recent proteomic analysis performed on egg yolk proteins contained in the plasma fraction, during the first half of incubation, reveals only few variations of their abundance: five proteins (vitronectin, α -fetoprotein, similar to thrombin, apolipoprotein B, and apovitellenin-1) showed a major increase in relative abundance, whereas 15 proteins showed a significant decrease in yolks of fertilized eggs (Rehault-Godbert *et al.*, 2014). The increase of abundance of some of these proteins might be explained by (1) secretion of proteins expressed by the embryo or its associated structures (such as α -fetoprotein, which is the embryonic form of serum albumin and that is present in a wide range of chicken embryonic tissues) or (2) progressive solubilization of some of these proteins from the fat-soluble fraction of yolk (granules) along with the decrease of yolk pH observed during incubation. On the other hand, proteins exhibiting a decreased abundance during this first half of incubation may be due to a selective use/assimilation of these proteins by the embryo at defined phases of its development. They include essentially immunoglobulins, hormone-binding proteins (transthyretin, which binds thyroid hormone) and the vitamin-binding proteins (retinol-binding protein 4 and riboflavin-binding protein). The progressive disappearance of these proteins is consistent with the development and the growth of the embryo as they all have been associated with many processes related to morphogenesis and organ development. Additionally, the fact that only 5 proteins have been reported to decrease during the first half of incubation confirms that up to day 11 of development, very small amounts of yolk nutrients are transferred to the embryo. This nutrient transfer relies on a very specialized structure namely the yolk sac, which develops at the very early days of incubation, from the developing gut of the embryo. It progressively spreads onto the vitelline membrane to totally surround the yolk by day 11 of development. In contrast to the first half of incubation, the second phase of incubation is characterized by prompt utilization of nutrients through the yolk sac, which is then fully matured, to support the rapid growth of the embryo. These yolk proteins serve as storage proteins for lipids, ions, iron, vitamins and hormones that are probably released locally in the embryo after absorption through the yolk sac. Moreover, these proteins probably undergo proteolytic degradation by digestive enzymes to provide free amino-acids for the embryo. It is also noteworthy that by the end of the 21-day incubation, the residual yolk sac is fully internalized into the abdominal cavity of the chick (followed by navel closing and healing). It is subsequently incorporated as part of the forming chick small intestine, and provides nutrients and protection (through remnant maternal immunoglobulins) to the newly hatched chick, until its own digestive tract and immune system become fully functional.

Conclusions

Vitellogenesis is under the control of estrogens and is temporally regulated in the ovary, the upper part of the reproductive tract. Yolk precursors are synthesized by the liver, secreted into the blood stream and incorporated into the forming yolks by receptor-mediated endocytosis. The largest yolk follicle will then ovulate in the oviduct and will be progressively surrounded by the other egg structures in very specialized segments of the oviduct. The resulting yolk consists of proteins bound or not to lipids that are all confined in a yolk container, delimited by the vitelline membrane, which in parallel anchors the egg yolk inside the egg. The progressive

assimilation of yolk components by the embryo initially relies on the vitelline membrane, an cellular protein layer bearing diverse functions: it triggers oocyte fertilization, it acts as a physical barrier against invading microbes and includes several antimicrobial proteins and peptides, and it drives the growth of blood vessels originating from the embryo to finally end in the so-called “yolk sac.” The function of the resulting “yolk sac” is to absorb, digest and transports nutrients composing the yolk toward the embryo (Yadgary *et al.*, 2014).

Egg yolk proteins are of major importance as some of them are specific to birds or oviparous species (vitellogenins, riboflavin-binding protein, ovalbumin). They have been shown to concomitantly accompany the evolution of animals from oviparity to viviparity and the transition of from egg-laying and yolk-dependent nourishment in birds and reptiles, toward the placentation and lactation in mammals (Tian *et al.*, 2010).

Altogether, recent proteomics on the egg yolk combined to bioinformatics analyses for functional protein annotation, and transcriptomics on the yolk sac at various time points of incubation, clearly brought new insights into (1) the identity and specificity of yolk proteins and, (2) the temporal regulation of the mechanisms by which yolk precursors are processed and absorbed via the yolk sac during embryogenesis. However, the role and the biological function of many egg yolk proteins and peptides with regards to the embryo development, remain fully opened.

Vitellogenesis and Yolk Proteins in Insects

Muhammad Tufail, King Saud University, Riyadh, Saudi Arabia; and Kobe University, Nada, Kobe, Japan

Introduction

All egg-laying species both vertebrates and invertebrates, including insects, provision their eggs with vitellogenin (Vg), a product of the Vg gene family, by a process known as vitellogenesis. During reproductive phase, the precursor Vg mRNA is expressed in large amounts in the female fat body, an organ functionally analogous to the vertebrate liver. It is then translated, secreted into the hemolymph and finally accumulated by the developing oocytes by membrane-bound receptors (VgRs) through receptor-mediated endocytosis (Tufail and Takeda, 2005, 2007, 2009a,b, 2012). In insects, Vg molecules undergo proteolytic cleavage, soon after their synthesis, and this post-transcriptional processing enables Vgs to carry with them the carbohydrates, lipids, and other nutrients to the oocytes (see for references therein a recent review by Tufail *et al.* (2014)). We have characterized six Vg molecules, both at biochemical and molecular basis including sequencing, from four insect species (*Periplaneta americana*, *Leucophaea maderae*, *Nilaparvata lugens* and *Lethocerus deyrollei*) and have shown by peptide mapping how these proteins undergo post-transcriptional proteolytic processing, and how quickly Vg subunits are sequestered by the oocyte when secreted into the hemolymph (Tufail *et al.*, 2000, 2001, 2005, 2007, 2010; Tufail and Takeda, 2002, 2004; Nagaba *et al.*, 2011). Once taken up by the competent oocytes, the Vgs are routed to the developing yolk body where they are crystallized and stored as vitellin (Vn), the major yolk protein, a nutritional source for the developing embryo.

The regulation of Vg genes is directly under the control of hormones at the transcriptional level. The sex- and tissue-associated, and hormone-mediated developmental specificities of Vg gene transcription have been reported for many insect species. The Vg gene is expressed in most, if not all, insect species in the female fat body, however, in some species, Vg mRNA has also been observed, although in smaller amounts, in larvae and males in the honeybee, and also that the distinct yolk proteins, YPs, were expressed in ovaries, in addition to the fat body, as was seen in *Cyclorrhapha* (see for references the recent review by Tufail *et al.* (2014)).

In insects, the YPs may be classified into four types: 1) The YPs (like Vgs of most insect species) that are synthesized in the fat body tissues in a sex-specific manner and taken up by the competent oocytes; 2) YPs that are produced both in the female fat body and ovarian follicle cells in a sex-specific manner and are incorporated into developing oocytes (YPs of *Cyclorrhapha*); 3) YPs that are synthesized in the ovarian follicle cells and incorporated into the developing oocytes in a sex-specific manner (egg-specific protein in *Bombyx mori*); and 4) Yps that are produced in the fat body cells in a sex non-specific manner and secreted into the hemolymph and internalized by the developing oocytes (such as the 30-kD protein of *B. mori*).

In this article, we provide our current understanding regarding vitellogenesis and yolk proteins in insects. We will briefly discuss the biochemical and molecular aspects of these (Vgs) important molecules in addition to the mechanisms that govern the regulation of Vg genes transcription. Subsequently, the uptake mechanism of Vg by the developing oocytes through its receptor (VgR) will be addressed.

Biochemical Traits of Insect Vgs

Insect Vgs are synthesized as a primary Vg gene product of ~200 kD, which is coded by a single Vg gene transcript of 6–7 kb (Tufail and Takeda, 2008). The primary Vg gene product undergoes post-translational proteolytic cleavage and splits into smaller polypeptides ranging from 50 to 180 kDa (see reviews: Tufail *et al.* (2005, 2014), Tufail and Takeda (2008, 2009c, 2012)). These cleaved Vg subunits are then assembled together, following extensive co- and post-translational modifications, and consequently secreted as big oligomeric phosphoglycolipoproteins (400–600 Da). Sometimes, Vgs are additionally cleaved in the ovary as being reported in the cockroach, *Leucophaea maderae* (Tufail and Takeda, 2002). The understanding that has been emerged from the recent molecular studies is that the Vgs molecules are cleaved in all insect species except Apocrita (higher Hymenoptera) where Vg gene product of ~180 kDa remains uncleaved (see reviews: Tufail and Takeda (2008, 2012)). However, the Vgs of some hemimetabolous insects (like cockroaches and the bean bug, *Riptortus clavatus*) are probably unique, cleaved into more than two subunit polypeptides (see reviews Tufail and Takeda (2008, 2009c)). In lieu, the YPs of *Cyclorrhapha* (higher Diptera) are quite different from the Vgs of other insects and also are not processed. These are much smaller (~45-kD) than those of other insects, and are also structurally similar to the mammalian triglycerol lipase gene family (see for references the reviews: Tufail and Takeda (2008, 2009c, 2012), Tufail *et al.* (2014)).

The comparison of protein primary structures has shown that insect Vgs are members of a greater superfamily of molecules known as large lipid transfer proteins, and are conserved among organisms as diverged as nematode and vertebrates (see for references the reviews: Tufail and Takeda (2008, 2012)) as has also been shown in our phylogenetic tree (Fig. 1). Our phylogenetic tree constructed based on 99 insect and non-insect Vg sequences reveals that insect Vgs are closer to arachnid and nematode Vgs as compared to vertebrate and crustaceans Vgs. Also, the crustacean Vgs represent the most diverged strongly supported cluster (with 100% bootstrap value) to all other Vgs (Fig. 1), and thus probably reflecting the divergence of the terrestrial and aquatic species. Furthermore, our phylogenetic analysis places all species in their respective taxa in a quite coherent manner, suggesting

Fig. 1 Phylogenetic tree constructed based on 99 Vgs from both vertebrates and invertebrates. Protein sequences were aligned using the CLUSTAL W program and used as input for a neighbor-joining tree construction program (MEGA6). Bootstrap values (500 replications) are indicated at each node. The scale indicates the distance (number of amino acid substitutions per site). The tree branches with red and black color represent non-insect and insect Vgs, respectively. The Vg sequences used for phylogenetic study were from the following species (accession number are shown in parentheses): *Blattella germanica* (AJ005115), *Leucophaea maderae* (Vg1: BAB19327; Vg2: BAD72597), *Periplaneta americana* (Vg1: BAA86656; Vg2: BAB32673), *Zootermopsis nevadensis*-Vg2 (KDR08463), *Apolygus lucorum* (AFW97644), *Cimex lectularius* (BAU36889), *Cyrtorhinus lividipennis* (AJ143739), *Geocoris pallidipennis* (ALN70475), *Graptopsaltria nigrofuscata* (BAA85987), *Homalodisca vitripennis* (AAZ06771), *Laodelphax striatella* (AGJ26478), *Neosidicoris deyrollei* (BAG12118), *Nesidiocoris tenuis* (AGV05363), *Nilaparvata lugens* (BAF75351), *Plautia stali* (Vg1: BAA88075; Vg2: BAA88076; Vg3: BAA88077), *Riptortus clavatus* (AAB72001), *Trigonotylus caelestialium* (BAJ33507), *Pediculus humanus corporis* (EEB18660), *Apis mellifera* (CAD56944), *Athalia rosae* (BAA22791), *Bombus hypocrite* (ACU00433), *Bombus ignites* (ACM46019), *Camponotus floridanus* (EFN64902), *Encarsia formosa* (AAT48601), *Formica exsecta* (AII96912), *Osmia cornifrons* (AIY25493), *Pimpla nipponica* (AAC32024), *Pteromalus puparum* (ABO70318), *Solenopsis invicta* (AAP47155), *Vespula vulgaris* (AER70365), *Rhynchophorus ferrugineus* (ALN38803), *Anthonomus grandis* (AAA27740), *Colaphellus bowringi*-Vg1 (AMK38869), *Harmonia axyridis* (AMP18919), *Octodonta nipae* (AKR04341), *Tenebrio molitor* (AAU20328), *Tribolium castaneum* (EFA11425), *Aedes aegypti* (AAA18221; Vg-B: AAQ92367; Vg-C: AAQ92366), *Anopheles albimanus* (AAV31933), *Anopheles culicifacies*-Vg1 (AE051020), *Anopheles darlingi* (ETN67132), *Anopheles gambiae*-Vg1 (AAF82131), *Anopheles minimus* (AHN13887), *Anopheles splendidus*-Vg1 (AGZ02020), *Anopheles stephensi*-Vg1 (ABD97990), *Anopheles subpictus* (AHM10344), *Culex quinquefasciatus* (EDS34783), *Culex tarsalis* (Vg1a: ADH04224; Vg1b: ADH04225; Vg2a: ADH04226; Vg2b: ADH04227), *Toxorhynchites amboinensis* (AAV31932), *Actias selene* (ABP63663), *Amyelois transitella* (XP_013200083), *Antheraea pernyi* (BAB16412), *Antheraea yamamai* (BAF45319), *Bombyx mandarina* (BAB32642), *Bombyx mori* (BAA06397), *Cadra cautella* (ALN38805), *Chilo suppressalis* (AMD78107), *Cnaphalocrocis medinalis* (AEM75020), *Corcyra cephalonica* (AHZ89334), *Danaus plexippus* (EHJ67298), *Helicoverpa armigera* (AGL08685), *Lymantria dispar* (AAB03336), *Mythimna separate* (AHG29547), *Operophtera brumata* (KOB78233), *Papilio machaon* (KPJ19580), *Papilio polytes* (XP_013148766), *Papilio xuthus* (KPJ04900), *Samia cynthia pryeri* (BAD91196), *Samia ricini* (BAB32641), *Saturnia japonica* (BAD91195), *Spodoptera exigua* (ALR35190), *Spodoptera litura* (ABU68426), *Dermacentor variabilis* (Vg1: AAW78557; Vg2: ABW82681), *Caenorhabditis elegans* (Vg1: CCD67565; Vg5: CCD63027; Vg6C: CCD70605), *Danio rerio*-Vg1 (AAK94945), *Gallus gallus* (AAA49139), *Ichthyomyzon unicuspis* (AAA49327), *Cherax quadricarinatus* (AAG17936), *Fenneropenaeus merguensis* (ACV32381), *Litopenaeus vannamei* (AAP76571), *Macrobrachium rosenbergii* (BAB69831), *Marsupenaeus japonicus* (BAD98732), *Metapenaeus ensis* (Vg1: AAM48287; Vg2: AAN40700; Vg3: AAT01139), *Pandalus hypsinotus* (BAD11098), *Penaeus monodon* (ABB89953).

that Vgs are still phylogenetically bound, although there exists a divergence among them, and can be used as a molecular marker to identify the phylogenetic inferences.

Molecular Aspects of Insect Vgs

As far molecular traits of insect Vgs are concerned, the sequence comparison of 81 Vgs from 72 insect species that belong to 7 different taxonomic groups (Fig. 1) demonstrates that they can be aligned confidently along their entire lengths, and represent the usual five particular subdomains of high sequence similarity. Also, the hallmarks that remain conserved at the C-terminus of most insect Vgs like a highly conserved motif GL/ICG, the polycysteines conserved at their specific sites, and the DGXR motif that exists 17–19 residues upstream of the GL/ICG in most of the insect species, were found existed (data not shown). Furthermore, the comparison of the consensus cleavage site motif RXXR indicates that its position is particularly conserved near the N-terminus of most of the non-apocritan Vgs and is flanked by polyserine domains (see for details the reviews by the same authors: Tufail *et al.* (2005), Tufail and Takeda (2008, 2009c, 2012)).

Vg Genes in Insects

Because of the prime role of Vgs in egg development/reproduction, Vg genes and/or their transcripts have been sequenced and characterized from several insect species representing diverse taxa (see reviews: Tufail *et al.* (2005, 2014), Tufail and Takeda (2008)) (also see Fig. 1). In insects, Vgs are coded by a single transcript of 6–7 kb, however, the number of Vg genes differs (one to several) in different species (see review: Tufail and Takeda (2008)). We have cloned/sequenced two Vg gene transcripts from each of the two cockroach species, *P. americana* and *L. maderae* (Tufail *et al.*, 2000, 2001, 2005, 2007; Tufail and Takeda, 2007, 2008). Multiple Vg genes have also been reported from other insect species including *Locusta migratoria*, *Riptortus clavatus*, *Plautia stali* and *Aedes aegypti*. Also, the sequences of multiple Vg genes have been identified by the whole genome analysis in several mosquito species comprising *Anopheles albimanus*, *Aedes aegypti*, *A. polynesiensis*, *A. albopictus*, *Ochlerotatus atropalpus*, *Oc. triseriatus*, *Culex pipiens* and *Toxorhynchites amboinensis* (see for references the review by Tufail *et al.* (2005, 2014), Tufail and Takeda (2008)). Nonetheless, the physiological role of multiple Vg genes in some insect species remains unclear. We speculate that different Vg genes may play different physiological roles. The extra-reproductive function of Vgs is not ruled out. Our hypothesis is also supported by the fact that the Vg gene is expressed in male honey bees suggesting that Vg may have also some additional function than as a yolk. Moreover, in crayfish, the plasma clotting protein is structurally similar to insect Vgs but is responsible for clot formation in crustacean blood. Recently, it has been reported that Vg gene is involved in regulation of hormonal dynamics, and has multiple coordinating effects on social organization of worker honey bees (see for reference the review: Tufail and Takeda (2008, 2009c), Tufail *et al.* (2014)). Delineating the overall and precise physiological roles of multiple Vgs should prove their significance.

Regulation of Vg Genes in Insects

The regulation of Vg genes in insects is controlled by hormones. The sex- and tissue-specific, and hormone-mediated developmental profiles of Vg gene transcription have been described for many insect species. In insects, the hormones reported for Vg gene transcription are juvenile hormone (JH), ecdysone, and neuropeptides (see reviews: Tufail and Takeda (2008), Tufail *et al.* (2014)). Among them, JH is the best-known for transcription of Vg genes and the consequent control of Vg synthesis. The regulation of Vg gene transcription depends on binding of hormone-receptor complex at hormone responsive elements (HREs) generally present in upstream regulatory region of the genes (see for references the above reviews). Although, molecular mechanism of JH remains clear, yet, several efforts have been made to identify JH receptor by separating a protein that binds to radio-labeled JH or JH analogues. Currently, two candidates are proposed for the JH receptor: 1) USP (ultraspiracle), the nuclear receptor; and 2) MET (Methoprene-tolerant), the bHLH-PAS protein family member. There is also a suggestion that JH functions through insulin-like peptide signaling pathway to regulate Vg gene expression (see for references the above reviews). The future research will clarify the reality.

In general, insects can be divided, based on the mechanism of hormonal regulation of Vg gene transcription, into three major groups: 1) Insects where only JH directs the regulation of Vg gene transcription. In fact, this hormone (JH) is well recognized in vast majority of insects for its involvement in Vg gene transcription; 2) Insects where ecdysteroid, a product from ovaries, is required for regulation of Vg gene requires in addition to the JH (such as Dipteran: mosquitoes and *Drosophila melanogaster*); 3) Insects like lepidopterans that require JH, ecdysteroids and additional hormones to regulate their reproductive biology. For more detail and references see the reviews by the same authors (Tufail and Takeda, 2008; Tufail *et al.*, 2014).

Uptake of Vgs by the Oocytes

The accumulation of yolk proteins during oogenesis, a process known as vitellogenesis, is the major route for the supply of proteins and lipids in developing oocytes. The vitellogenesis is triggered, in many insect species, by the JH where other factors such as neural or endocrinological ones also play important roles. Recently, the effect of indolamines as neurohormones on the onset of

vitellogenesis has been identified, and proved that vitellogenesis is upregulated by the injection of tryptamine (Tn) and *N*-acetyl-tryptamine and that the action of Tn was both direct and indirect via JH regulation, evidence of cross-talk between monoamines and sesquiterpenoid routes (Kamruzzaman *et al.*, 2016). The uptake of Vgs by the competent oocytes, a typical phenomenon of all oviparous species including insects, is accomplished through receptor-mediated endocytosis (see reviews: Tufail and Takeda (2009a,b,c, 2012)). In this episode, follicle cells are in fact the key players to regulate Vg uptake by providing a pathway for oocytes to access Vg in a JH-dependent fashion during vitellogenesis (see for references the review: Tufail and Takeda (2012)). In insects, the accumulation of Vgs is facilitated by endocytotic machinery via VgRs of the low density lipoprotein receptor (LDLR) gene family (see above reviews) (Fig. 2). We have characterized VgRs, both at biochemical and molecular basis including sequencing, from two cockroach species (*P. americana* and *L. maderae*), and provided evidence that two distinct female-specific proteins Vgs (Vg1 and Vg2) are accumulated by their receptor (VgR) in the cockroach, *P. americana* (Tufail *et al.*, 2000, 2001, 2005; Tufail and Takeda, 2005, 2007). The VgRs primary proteins are highly conserved in organisms as diverged as insects, frogs and chickens, and this is probably because of their physiological role. The receptors (VgR) where Vg anchors are confined in coated pits on the surface of growth competent oocytes. After binding, the ligand/receptor (Vg/VgR) complexes concentrate in clathrin-coated pits that invaginate and pinch off to form intracellular coated vesicles. These vesicles then carry the Vg product to an endosome, which directs subsequent intracellular transportation of both the protein (Vg) and the receptor (VgR). The acidic environment of the endosome results in dissociation of Vg/VgR complexes, which results in recycling of the VgR back to the oocyte surface while Vg is transported to the mature yolk bodies, where it is processed and stored as Vn, the nutritional source for the future embryo (see for references and detail the reviews by the same authors: Tufail and Takeda (2009a,b,c, 2012)) (Fig. 2). The proteins accumulated by oocyte in addition to Vg include lipophorin, arylphorin, microvitellogenin and several other follicle specific proteins, however, the receptor specificity of these proteins

Fig. 2 A schematic representation of how the major yolk protein precursor Vg is endocytosed in the insect oocyte. The Vg molecules carried by the hemolymph pass through the spaces formed between follicular epithelial cells (patency) and bind to its counterpart, the VgR in the clathrin-coated pits, which are accumulated in coated vesicles and then, after losing clathrin coats, in early endosomes. These early endosomes then fuse and form the yolk bodies whereas VgR is recycled and goes back to oocyte membrane. Once Vg becomes a part of the egg yolk, it is called vitellin (Vn), a nutritional reserve for the future embryo. This diagram is produced based on Tufail, M., Takeda, M., 2012. Insect yolk proteins and their role in reproduction. In: Tufail, M., Takeda, M. (Eds.), *Hemolymph Proteins and Functional Peptides: Recent Advances in Insects and other Arthropods*, vol. 1. Dubai, UAE: Bentham Science Publishers, pp. 1–16.

remains unclear. Moreover, the oocyte cytoplasm also comprises a number of lipid droplets together with triglycerides, phospholipids and granules of glycogen in addition to some proteases taken up by the oocytes for yolk proteolysis during embryogenesis.

Immediately after vitellogenesis, the vitelline membrane, a thin protein sheet composed of several proteins (with molecular mass of 14–130 kD) and regulated by 20-hydroxyecdysone, is secreted at the inner surface of the follicle cells, and a chorion is synthesized. The chorion, a product of follicle cells composed of a number of sclerotized proteins, is placed on the egg, before fertilization, while the egg still exists in the ovary. As soon as, the chorion is secreted, this layer forms an impermeable covering except micropyle, a specialized opening through which a sperm enters. When emission of chorion is accomplished, the mature follicle cells are degraded and leave the chorion as the outermost covering or shell of the egg which is then fertilization in the median oviduct and oviposited (see for references and detail the reviews by the same authors: Tufail and Takeda (2009a,b,c, 2012)).

Concluding Remarks

Recent molecular studies have added immensely in our understanding about biochemical and structural aspects of Vgs, about their biosynthesis, processing and transcriptional regulation in addition to their uptake mechanism by the developing oocyte. Yet, many questions need to be answered. Vg structures appear to be conserved although in certain amino acid residues/motifs, in organisms as diverged as nematode and vertebrates. This structural maintenance in Vgs of varied taxa is, perhaps, because of their unique function as a yolk. However, why there exist multiple Vg genes in some insects and why insect species diverge in deploying different hormones to regulate their reproductive physiology remains unclear. We have proposed that different Vg genes may have different physiological roles (Tufail and Takeda, 2008, 2012). The physiological function of Vg other than yolk is not ruled out especially when Vg gene transcription has been detected in honey bee males; also connection of Vg gene in hormonal dynamics in addition to its multiple coordinating effects on social organization in worker bees has been reported. Moreover, antioxidant activities of Vgs and their role in extending lifespan of honey bee and *C. elegans* in addition to their involvement in promoting macrophage phagocytosis in fish have been reported. Also recently, Vg has been described to decrease the parasite-killing efficiency of the antiparasitic factor TEP1 (thioester-containing protein 1) in *Anopheles gambiae*, and has shown anti-bacterial activity in *Bombyx mori*, thus suggesting some link of this protein with immunity (see for references the reviews: Tufail and Takeda (2008, 2009c), Tufail et al. (2014)). Future studies must elucidate the extra-reproductive roles of Vgs in insects. Also, the molecular mechanism of hormonal regulation of Vg gene transcription, especially for JH, remains another hot issue for future research. Next, the precise mechanism of the endocytotic machinery for uptake of Vgs by the oocyte remains unclear.

Glossary

Androgenic gland A male specific tissue associated with the sperm ducts (vas deferens); is an endocrine gland, and produces androgenic gland hormone, which regulates the sexual differentiation of the male reproductive system.

Consensus cleavage sites Cleavage sites that possess the amino acid sequence R-X-K/R-R that are targeted by enzymes of the subtilisin family, and are found within the crustacean vitellogenin molecule.

Ecdysteroids Collectively refers to substances related to 20-hydroxyecdysone, the molting hormone in insects and crustaceans; is also implicated to have a role in reproduction and embryogenesis.

Eyestalks The anatomical part of the decapod crustacean that supports the compound eye; harbors the X-organ/sinus gland complex, a neurosecretory tissue that produces numerous hormones that control molting, reproduction, and metabolism.

Farnesoic acid The precursor of methyl farnesoate in Crustacea. Thought to function in the regulation of molting and metamorphosis.

Follicles Ovarian cell layer of epithelium immediately surrounding an oocyte; regulates transport between blood/hemolymph and the oocyte. May also secrete certain components of the egg.

Gonadotropin-releasing hormone (GnRH) A neuro-hormone consisting of 10 amino acids that is produced in the arcuate nuclei of the hypothalamus. Stimulates the synthesis and secretion of the vertebrate gonadotropins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH). Additionally implicated to have a reproductive role in molluscs.

Hemolymph The arthropod equivalent of blood; includes cells that are referred to as “hemocytes” and utilizes hemocyanin in most cases as the carrier of oxygen.

Hepatopancreas Serves as a digestive organ with pancreatic function in crustaceans and is also known as the “midgut gland”; established to be a major site of vitellogenin production in decapods.

Hermaphroditic Indicates an animal which can change from male to female (protandric) or from female to male (protogynous). In Crustacea, many protandric species exist.

Intersex An abnormal sexual phenotype; an individual having both male and female secondary sexual characteristics.

Mandibular organs Endocrine gland associated with the mandibular tendon; produces methyl farnesoate, and is negatively regulated by mandibular organ-inhibiting hormone (MOIH); located anteriorly above the Y-organs.

Perivitelline fluid Fluid that fills the space between the vitelline membrane and the zona pellucida. Appears in the ovum immediately following fertilization.

Sesquiterpenoids Chemical substances which consist of three isoprene (C_5H_8) units; examples include juvenile hormone, methyl farnesoate, and farnesoic acid.

Introduction

This entry discusses the current state of knowledge concerning yolk proteins in crustaceans and molluscs, covering structural facets, the hormonal control of their production, and their usage as a source of nutrients during embryogenesis. As detailed below, both animal groups include numerous species that are of economic importance and are consumed by humans; such species are the target of aquaculture and commercial fishing activity. From this perspective, it has been important to elucidate their reproductive mechanisms so that the life cycle can be closed and the animals reared efficiently in captivity; understanding the fundamentals of yolk proteins is requisite in this regard. Obviously, both groups are classified as invertebrates; Mollusca is a phylum unto itself, while Crustacea constitutes a sub-phylum within the Phylum Arthropoda. In addition, many crustacean species, while not a source of food for human consumption, are well-studied, and their reproductive ability serves as a means for assessing the state of the environment and the possible presence of endocrine disruptors. While much of the knowledge concerning yolk proteins in these animals is unified and cohesive, there exists a diversity of structure for the yolk proteins themselves. Nevertheless, structure often reflects taxonomic classification, which is especially apparent in the case of decapod crustaceans, discussion of which follows immediately below.

Crustacea

Yolk Protein Structure in Decapod Crustaceans

Decapod Crustacea constitute an order within the crustacean class Malacostraca, comprising over 10,000 species. Within this order are contained several infraorders, e.g., *Penaeidea* (marine shrimp), *Caridea* (marine, estuarine and freshwater shrimp), *Astacidea*

(lobsters, crayfish), *Palinura* (spiny lobsters), *Anomura* (mud-borrowing shrimp, hermit crabs, other) and *Brachyura* (marine, estuarine and freshwater crabs), among others. This order, therefore, comprises the majority of crustacean species that have economic value and are the targets of aquaculture and/or commercial fishing activities. As is well-known, shrimp culture is an established significant world-wide industry having a production scale of over 4 million tons per year, corresponding to a market volume of over 20 billion U.S. dollars (FAO, 2014). In this regard, much of the research on crustacean reproduction, and hence, crustacean yolk proteins, has focused on that of decapod species, especially for those where it is of importance to develop technology to close the life cycle in captivity, such as that for the whiteleg shrimp, *Litopenaeus vannamei* which constitutes over 80% of the world's aquaculture.

The structure, processing, and site of production of vitellogenin has been an important research topic in decapod crustaceans for nearly 45 years, and it is during approximately the past 15 years that this knowledge has come to be generally complete and unified. This body of research has shown that crustacean vitellogenins differ a great deal in terms of amino acid sequence and certain structural features, from those of other animal groups, even from insects, which are also included in the phylum Arthropoda. However, vitellogenesis in Crustacea follows the same basic process in which vitellogenin is produced in specific tissues as a large yolk protein precursor and is subsequently processed into smaller molecules. The end product is vitellin, which is accumulated in developing oocytes to serve as a source of nutrients for the developing embryo.

Initially, studies focusing on crustacean vitellogenins utilized electrophoretic or immunological techniques, yielding information on molecular weight and subunit composition. Many workers also characterized amino acid composition, as well as lipid and carbohydrate content. For example, in the giant freshwater prawn, *Macrobrachium rosenbergii*, various research groups found that vitellogenin was composed of three subunits, of molecular weights of around 200, 100 and 90 kDa, while vitellin consisted of two immunologically equivalent subunits of 90 kDa (Wilder *et al.*, 2010).

Later studies employing molecular biological techniques enabled workers to characterize vitellogenin cDNA and elucidate the primary structure for this molecule. The first report of a complete primary sequence in a crustacean species was accomplished by Tsutsui *et al.* (2000), in the kuruma prawn, *Marsupenaeus japonicus*. Tsutsui *et al.* (2000) used N-terminal amino acid sequence information, and the method of "library walking", to obtain a full-length cDNA encoding 2587 amino acids. This vitellogenin precursor contained two consensus cleavage sites R-X-K/R-R targeted by enzymes of the subtilisin family. Thus following, vitellogenin structure has been clarified in nearly 20 decapod species, including prawns/shrimps, crabs, crayfishes and burrowing shrimp. Thus far, all species have shown high levels of identity, the degree of which reflects phylogenetic classification. For example, members of the same family (in the case of Penaeidae) have identity levels of around 90% throughout the entire molecule. In less-related species, the degree of identity is especially high in the first part of the molecule, but somewhat lower in the middle and latter parts of the molecule. Fig. 1 shows a schematic diagram of the vitellogenin molecule and its confirmed/putative processing sites for three species elucidated by the authors of this entry and other co-workers. The percent of amino acid identity for *M. rosenbergii* and *M. japonicus* compared to *Pandalus hypsinotus* for the first and latter parts of the molecule are shown.

Of interest, crustacean vitellogenins (meaning decapod crustaceans) are lacking in polyserine domains that are found in most invertebrate and vertebrate vitellogenins. In the latter, such stretches of serine residues often flank processing sites targeted by subtilisin, possibly creating a beta-pleat arrangement that exposes the processing site to the enzyme (Chen *et al.*, 1997). Nevertheless, decapod vitellogenins do contain 2–3 consensus cleavage sites, e.g., R-X-K/R-R, and almost all studies covering nearly 20 decapod species have documented that actual cleavage occurs at the first of these sites, conserved around or after the 700th residue in the primary structure (for example, in *M. rosenbergii*, Arg⁷⁰⁷-Arg⁷¹⁰, where cleavage occurs between amino acid residues 710 and 711 (Okuno *et al.*, 2002)). It can now be said that the primary structure of decapod crustacean vitellogenin generally consists of around 2500 amino acids, and is processed initially at the hepatopancreas, and once more in the hemolymph, finally yielding three vitellins which are then found in the developing ovaries. As for the site of synthesis, vitellogenin mRNA expression is seen in only in the hepatopancreas in *M. rosenbergii*, *P. hypsinotus*, and similarly-classified species. In penaeid species, such expression occurs in both the hepatopancreas and the follicle cells of the ovaries. Processing mechanisms for vitellogenin synthesized at the ovaries is unclear, but there are no major differences in molecular structure from that synthesized at the hepatopancreas.

Vitellogenin, and more particularly, the final vitellin molecule is in general, are regarded to have various modifications, although full profiles have not been elucidated for the majority of species. These modifications may include glycosylation, metal binding, lipid conjugation, carotenoid conjugation, and hormone binding, particularly of ecdysteroids. The purpose of such modifications may be to assist in bringing necessary nutrients, in addition to vitellin itself, into the eggs for purposes of embryonic development, or ecdysteroids to help the embryo with molting until it can produce its own source of hormone. This topic is reviewed in Wilder *et al.* (2010), and the reader is referred to this source for further information. However, of note, Khalaila *et al.* (2004) elucidated fully the nature of carbohydrate moieties in vitellogenin in the crayfish, *Cherax quadricarinatus*. These authors employed mass spectrometry and other techniques and found, for example, that putative N-glycosylation sites, at Asn¹⁵², Asn¹⁶⁰, and Asn²⁴⁹³ were glycosylated with high-mannose glycans. Glycosylation of vitellogenin and vitellin is postulated to be important in processing and transport, in addition to its nutritional role.

Hormonal Control of Yolk Protein Synthesis in Decapod Crustaceans

Since the 1940s, eyestalk ablation has been known as a methodology for stimulating ovarian maturation and spawning in crustaceans. The rationale behind this methodology is the presence of inhibitory factor in the eyestalks, which are presently referred to as vitellogenesis-inhibiting hormone (VIH) (also gonad-inhibiting hormone; GIH). Thus, vitellogenin synthesis is controlled

Fig. 1 Schematic diagram of the vitellogenin molecule and its confirmed/putative processing sites for several of the first decapod species that were elucidated. Percent (%) amino acid identity for *Macrobrachium rosenbergii* and *Marsupenaeus japonicus* compared to *Pandalus hypsinotus* are shown for the first and latter parts of the molecule. Confirmed processing sites are indicated by solid arrows; putative processing sites are shown by open arrows. Reproduced from Tsutsui, N., Kawazoe, I., Ohira, T., *et al.*, 2000. Molecular characterization of a cDNA encoding vitellogenin and its expression in the hepatopancreas and ovary during vitellogenesis in the kuruma prawn, *Penaeus japonicus*. Zool. Sci. 17, 651–660 and Wilder, M.N., Okumura, T., Tsutsui, N., 2010. Reproductive mechanisms in Crustacea focusing on selected prawn species: Vitellogenin structure, processing and synthetic control. Aqua-BioSci. Monogr. 3, 73–110.

negatively via the functioning of VIH. VIH is synthesized in the X-organs, and is then stored and/or secreted into the hemolymph from the sinus gland of the eyestalks. This tissue, a collection of neurosecretory cells, is known generally as the X-organ/sinus gland complex, and is responsible for the production of a host of important neuropeptides. Notably among these are members of the crustacean hyperglycemic hormone (CHH) family. CHH-family peptides also include VIH, molt-inhibiting hormone (MIH), and mandibular organ-inhibiting hormone (MOIH). The mature peptide of a typical CHH-family member is comprised of 72–78 amino acids with six conserved cysteine residues. These peptides are considered to have multiple functions and immunological cross-activity among themselves. For example, CHH exhibits hyperglycemic action, but also possesses inhibitory effects on molting and reproduction.

Eyestalk ablation is frequently used to induce ovarian maturation by removing the source of VIH, both in a laboratory situation, and in hatchery operations for commercially important species of shrimp. However, this procedure leads to potential hormonal imbalance, as it also removes the animal's means of producing other important hormones. Therefore, understanding of the physiological functioning of VIH is important for not only purposes of elucidating reproductive mechanisms more fully, but also for developing alternative methods to eyestalk ablation. The first report focusing on the dynamics of vitellogenin and VIH levels in the hemolymph in relation to molting was conducted in *L. vannamei* by Kang *et al.* (2014). It was seen that VIH levels in hemolymph fluctuated in adults and sub-adults. In adults, hemolymph VIH surged preceding the peak of vitellogenin levels that occurred around intermolt stage C (Fig. 2), although this pattern was not as clear in sub-adults. Although new information on VIH has accumulated in decapod crustaceans, the cues that actually trigger vitellogenesis, and how VIH prevents this in concert with other factors, remains to be elucidated. In this regard, the stimulating effects on vitellogenesis by putative vitellogenesis-stimulating hormone (VSH) which is thought to be secreted by the brain or/and thoracic ganglia, have been examined in several decapod species. It is possible that this VSH is either a protein or peptide hormone.

Hormonal control of vitellogenesis is also closely related with the molt cycle. As an additional candidate to VSH as a trigger of vitellogenesis, many workers have focused on methyl farnesoate (MF). MF, a sesquiterpenoid, and the precursor to juvenile hormone (JH) in insects, has been detected in Crustacea. Farnesoic acid (FA) is the precursor to MF in Crustacea, and is secreted from the mandibular organs which are controlled negatively by MOIH. MF is considered to act in developmental and reproductive roles in a similar fashion to JH in the case of insects, as JH has not been detected in the crustaceans. Regarding reproduction, the effects of MF have been tested in over 10 species of crustaceans both *in vivo* and *in vitro*. Stimulatory effects on ovarian maturation have been reported in seven species; nevertheless, the involvement of MF during vitellogenesis has not been confirmed for a full spectrum of species (see Subramoniam (2011) for review).

Neurotransmitters, such as serotonin (5-hydroxytryptamine; 5-HT), have also been reported to be involved in ovarian maturation in several decapod crustaceans. Ovarian maturation was induced after 5-HT injection in the Indian white prawn, *Fenneropenaeus*

Fig. 2 Schematic diagram for the dynamics of important reproductive parameters in crustaceans based on data obtained for *Litopenaeus vannamei*. Relative levels for vitellogenin and vitellogenesis-inhibiting hormone (VIH) in the hemolymph are shown together with changes in gonado-somatic index (GSI). Changes in circulating vitellogenin levels are synchronized with those for GSI change, but not for those of VIH. When vitellogenin levels were seen to peak, VIH showed low concentrations in the hemolymph. Reproduced from Kang, B.J., Okutsu, T., Tsutsui, N., *et al.*, 2014. Dynamics of vitellogenin and vitellogenesis-inhibiting hormone levels in adult and subadult whiteleg shrimp, *Litopenaeus vannamei*: Relation to molting and eyestalk ablation. *Biol. Reprod.* 90 (1), 12, 1–10.

indicus, the banana shrimp, *Fenneropenaeus merguensis*, the lobster, *Homarus americanus*, the whiteleg shrimp, *L. vannamei*, the red swamp crayfish, *Procambarus clarkii*, the black tiger prawn, *Penaeus monodon*, and in the fiddler crab, *Uca pugilator*. It is considered that actions of 5-HT are to cause the release of VSH (from the thoracic ganglion and/or the brain) or vitellogenesis-stimulating ovarian hormone. Furthermore, this process may be inhibited/mediated by dopamine. Spiperone, which is a dopamine antagonist, has also been reported to induce ovarian maturation in crayfishes *C. quadricarinatus*, and *P. clarkii* and in the giant freshwater prawn, *M. rosenbergii* by *in vivo* treatment (Subramoniam, 2011).

Other factors that are also reported to be involved in ovarian maturation include androgenic gland hormone (AGH). AGH, which is produced in the androgenic glands, in some instances shows similar effects with VIH. In intersex males in *C. quadricarinatus*, vitellogenin syntheses can be induced by removal of the androgenic glands. In the hermaphroditic caridean prawn, *P. hypsinotus*, vitellogenic oocytes appear after degeneration of the androgenic glands (Subramoniam, 2011).

Uptake and Utilization of Yolk Proteins in Decapod Crustaceans

As detailed above, vitellogenin and vitellin have been extensively characterized in decapod crustaceans; in addition, there is a burgeoning literature on the crustacean vitellogenin receptor (VgR), although fewer species have been characterized. Vitellogenin enters the developing oocytes from the hemolymph via receptor-mediated endocytosis similarly to other oviparous animals, and once vitellogenin is deposited within the oocytes, VgR is re-circulated back to the oocyte membrane. The first molecular characterization of VgR in Crustacea was accomplished by Tiu *et al.* (2008) in the black tiger prawn, *P. monodon*. These authors obtained a 6.8 kb cDNA for VgR, with the deduced amino acid sequence being comprised of 1943 residues.

In the kuruma prawn, *M. japonicus*, a putative ovarian lipoprotein receptor was obtained having a full-length cDNA of 3598 bp, and the deduced amino acid sequence encoded 1120 amino acid residues (Mekuchi *et al.*, 2008). Although this molecule is much smaller than the VgR molecule in *P. monodon*, both sequences share common structural features characteristic of the LDL-receptor family, such as the ligand-binding domain, the epidermal growth factor (EGF) precursor domain, an EGF-like domain, and a trans-membrane region. Similarly, in terms of tissue-specific gene expression, both are expressed exclusively in the ovary, further underlining their respective roles in reproduction. More recently, Roth and Khalaila (2013) characterized the VgR molecule and its expression dynamics in *M. rosenbergii*, also illustrating the importance of its functioning during vitellogenesis in decapods.

Vitellin accumulated in the oocytes then serves as a source of nutrients during the ensuing process of embryogenesis, and is often referred to as “lipovitellin” at this point. Most decapod species including shrimps, crabs, and lobsters brood an egg mass which is held externally on the abdomen until the embryos hatch. This period may range from several days to several months, depending on species and habitat. Penaeid shrimp and prawns are the exception, and broadcast their eggs into the surrounding water, to generally hatch within 24 h. The egg also contains hydrolytic enzymes and proteases that break down the lipovitellin and make lipids, proteins, and amino acids available for usage.

This phenomenon has been closely studied in brine shrimp (*Artemia salina*), which belongs to the crustacean class Branchiopoda, and to a certain extent, in decapod crustaceans such as the freshwater shrimp, *Macrobrachium borelli* (Garcia *et al.*, 2008). *M. borelli* broods an egg mass for nearly 40 days, during which time embryogenesis occurs; lipovitellin which is firstly accumulated in the ovaries is also found in developing eggs. In the early embryonic stages, lipovitellin consists of the 112 kDa and 94 kDa subunits, but is degraded to smaller subunits of 70 kDa, and finally 43 kDa. It is likely that other *Macrobrachium* genus species engage in similar means of vitellin usage during the period while eggs are developing.

Yolk Protein Structure and Related Aspects in Other Crustacean Groups

In crustaceans other than in the Order Decapoda, yolk proteins encompassing both vitellogenin and vitellin have been purified and characterized in a variety of species, e.g., in the following: Class Maxillopoda, Subclass Copepoda (Orders Siphonostomatoida, Cyclopoida, Calanoida, Harpacticoida), Class Branchiopoda, and Class Malacostraca (Orders Mysida, Amphipoda). However, much fewer information has been reported in these crustacean groups compared to that available in decapod crustaceans.

In copepods, vitellogenin genes have been identified in four species, *Lepeophtheirus salmonis* (Siphonostomatoida), *Paracyclopina nana* (Cyclopoida), *Pseudodiaptomus annandalei* (Calanoida), *Tigriopus japonicus* (Harpacticoida). It was suggested that most copepods possess two copies of vitellogenin genes, because two vitellogenin genes were reported in all of the above species with the exception of *P. annandalei*. The major synthetic site for vitellogenin is in the hepatopancreas and/or the ovary in decapod crustaceans; however, extra-ovarian sites are reported as well in other crustacean groups. In the case of the salmon louse, *L. salmonis* (Siphonostomatoida), in which a hepatopancreas does not exist, vitellogenin is synthesized in the subcuticular tissue, but not in the ovaries. Circulating vitellogenin secreted into the hemolymph is thus accumulated into the oocytes. The cleavage of vitellogenin (225 kDa) in this species occurs for only one vitellogenin molecule, yielding two subunits (95 kDa and 120 kDa) of vitellin present in eggs, but not for the other vitellogenin (also of 225 kDa). The identity of the deduced amino acid sequences between two *L. salmonis* vitellogenin cDNAs is 23%, meaning that multiple vitellogenin genes (vitellogenin paralogues) may be duplicated in a species-specific manner (Dalvin *et al.*, 2011).

In viewing the structure of these vitellogenin cDNAs, it is observed that both an N-terminal “vitellogenin N domain” and a C-terminal “VWD domain” exist. The “vitellogenin N domain” is a lipoprotein amino terminal region which is thought to be involved in lipid transport, and the “VWD domain” is a von Willebrand factor type D domain. It is noted that the consensus R-X-K/R-R cleavage site of decapods is not present in the “vitellogenin N domain”. However, a GL/ICG motif characteristic of the “VWD domain” is sometimes found in decapod crustaceans with GLLG being substituted for GL/ICG.

Daphnia magna (Branchiopoda: Diplostraca) also possesses two vitellogenin genes: the cDNAs for both are around 6000 bp-long, and their identity is 91.5% at the level of deduced amino acid sequence. The genomic DNA for both genes have also been reported (Tokishita *et al.*, 2006). One prominent feature in these deduced amino acid sequences is the presence of a superoxide dismutase (SOD)-like domain in the N-terminal, which shows significant homology to that of Cu/Zn-type superoxide dismutase. As with copepods, these vitellogenin cDNAs also harbor an N-terminal “vitellogenin N domain” and a C-terminal “VWD” domain. In terms of phylogenetic analysis, *D. magna* vitellogenin is more closely related to insect vitellogenins; however, the SOD-like domain itself is closely related to viral and bacterial SODs. The *D. magna* vitellogenin molecule is approximately 220 kDa in eggs at the early stages, and is primarily cleaved into three subunits.

A high molecular weight vitellin has been reported in *Neomysis integer* (Malacostraca: Mysida), having a molecular mass of 700 kDa and being composed of six subunits (51, 55, 62, 66, 84 and 89 kDa). In particular, mysid crustaceans are often used in toxicity tests such as that for endocrine-disrupting substances, because their life cycles are well-understood, and how they grow and reproduce in context of environmental factors including temperature, salinity, food availability, and light, is widely documented. Nevertheless, the purification of vitellin has been carried out only in two species, e.g., *Americamysis bahia* and *N. integer* for purposes of developing an enzyme-linked immunosorbent assay (Ghekiere *et al.*, 2004). In this regard, several species of crustaceans have been used as model species for toxicity testing in context of the presence of environmental endocrine disruptors, which may alter the life cycle or bring about intersexuality. Many studies on protein levels or gene expression for vitellogenin in such crustaceans have therefore been conducted for purposes of determining how the exposure of animals to environmental disruptors affects such parameters in terms of their utility as biomarkers. However, the use of vitellogenin as a biomarker in crustaceans can often be difficult, because many aspects of their endocrine mechanisms remain unclear, compared with those of fish, for example. Therefore, it is not always easy to define the exact factors that cause endocrine disruption in crustaceans, even if sexual differentiation is disrupted. This is because the malleability of sexual differentiation occurs naturally in crustaceans, where many species exhibit intersexuality and hermaphroditism. Further basic research on reproductive mechanisms and the relationship between the life cycle and environmental influence is required in order to develop more effective usages of vitellogenin as a biomarker.

Mollusca

Yolk Protein Structure in Molluscs

The Phylum Mollusca is composed of seven classes, namely Aplacophora (no shell), Polyplacophora (chitons), Monoplacophora (single external shell), Gastropoda (snails and slugs), Cephalopoda (octopuses and squids), Bivalvia (clams, oysters, mussels, cockles, scallops, and other) and Scaphopoda (tusk shells) comprising over 80,000 species. The classes Gastropoda, Cephalopoda and Bivalvia harbor the majority of the economically important species that are the targets of aquaculture and/or commercial fishing activities. Total world-wide molluscan culture production has exceeded 16 million tons per year, corresponding to a market volume of over 19 billion U.S. dollars, while total capture production reached 7.7 million tons per year as of 2014 (FAO, 2014).

Until the early 1990s, there had been few reports detailing yolk formation or the characteristics of yolk proteins in molluscs. However, with the recent development and application of molecular biological tools to research in this field, certain advances have been made concerning the structure and characteristics of molluscan yolk proteins. Starting with gastropods, the lipid and protein composition of the perivitelline fluid of the eggs of the freshwater snail, *Pomacea canaliculate*, was investigated and two

lipoproteins (PV1 and PV2) and one lipoprotein fraction (PV3) were detected (Garin *et al.*, 1996). These represented 57.0%, 7.5%, and 35.5%, respectively, of this species' total egg proteins. PV1 was shown to be a glyco-carotene-protein complex having the characteristics of a very high-density lipoprotein (VHDL), containing 0.33% lipid comprised of mainly free sterols and phospholipids. Furthermore, this particle was observed to have a molecular weight of 300 kDa and be composed of three subunits of 35, 32, and 28 kDa. The PV2 particle was a VHDL of 400 kDa containing 3.75% lipid. Here, the major lipid classes consisted of free sterols and phospholipids, also having significant quantities of energy-providing triacylglycerides and free fatty acids. The subunits of PV2 corresponded to two apoproteins of 67 and 31 kDa. The PV3 particle in terms of density corresponded to high-density lipoprotein (HDL). It could be fractionated into two sub-fractions, which were referred to as "h" and "p". Fraction "h" contained 5.16% lipids, mainly free sterols, phospholipids, and free fatty acids, and two particles of 100 and 64 kDa. Fraction "p" was composed of a single particle of 26 kDa that contained 9.5% lipid, representing 30% of the total egg lipids. These three fractions are thought to serve as the major supply of lipids and amino acids to the developing embryo (Garin *et al.*, 1996).

Regarding the site of synthesis of molluscan lipoproteins, Dreon *et al.* (2002) investigated this for PV2; tissues (albumen gland, gonad-digestive gland complex, and muscle) from vitellogenic females were incubated *in vitro* with ^{14}C -leucine at 25°C for 12 h, after which soluble proteins from tissue homogenates and medium were analyzed for de novo protein synthesis. Using electrophoresis and high performance liquid chromatography (HPLC), radiolabeled proteins were quantified by liquid scintillation. Two radiolabeled proteins (67 and 31 kDa) originating from the albumen gland co-migrated with the subunits of PV2, and western blot analysis also confirmed the presence of PV2 only in the albumen gland. Other experimentation, such as *in vivo* injection of ^3H -leucine into adult females and immunochemical analysis of all tissues of the snail again confirmed the presence of PV2 only in the albumen gland. In this way, the above authors revealed that this tissue is the sole site of PV2 synthesis. The PV2 subunits were further characterized in terms of N-terminal amino acid sequence, but they showed no homology to other known proteins (Dreon *et al.*, 2002).

In bivalves, a female specific protein (FSP) was identified and purified from the ovary of the Japanese scallop, *Patinopecten yessoensis*, using a combination of immunological and chromatographical techniques including hydroxylapatite chromatography and gel filtration (Osada *et al.*, 1992). The molecular weight of FSP was determined to be approximately 450 kDa. Three other female specific proteins, two having the same molecular weight and the other being 700 kDa, showed differing electrophoretic mobility on native polyacrylamide gel electrophoresis, but did cross-react with antiserum against purified FSP. No FSP was immunologically detected in the extract of the digestive diverticula or in concentrated hemolymph. Extracts from the ovaries of Farrer's scallop, *Chlamys farrerii nipponensis*, and blue mussel, *Mytilus edulis*, cross-reacted with FSP antiserum, but a similar reaction was not seen for the Pacific oyster, *Crassostrea gigas*. The quantity of FSP in ovarian extract from the Japanese scallop increased with the advancement of ovarian development, and this protein itself was found localized in the oocyte cytoplasm. It is considered that the FSP is formed as a yolk protein complex in the ovary being possibly composed of four molecules synthesized from the same source. Furthermore, it has been shown that the antigenicity of FSP is partially conserved among bivalve species (Osada *et al.*, 1992). Regarding the above, the reader is also referred to a recent review on endocrine control in bivalve mollusks by Osada and Matsumoto (2016).

In cephalopods, oocyte growth has been studied in the cuttlefish, *Sepia officinalis*, and is characterized by a high level of yolk protein expression; these yolk proteins serve as a reserve of nutrients for use in embryonic development (Gaudron *et al.*, 2005). The combined techniques of SDS-PAGE and mass spectrometry allowed the identification of two yolk proteins referred to as vitellin 1, having a molecular weight of around 150 kDa, and vitellin 2, being greater than 250 kDa in molecular weight; these vitellins were detected in the ovarian follicles and the vitelline vesicles, and found to be a component of oocyte yolk. Vitellins 1 and 2 showed no sequence homology as demonstrated by MS/MS analysis of peptides fragments obtained by tryptic digestion. In addition, the anterior vitelline vesicle associated with the embryo contained a 100 kDa protein that shared a high degree of sequence homology with vitellin 2, suggesting that this protein undergoes post-translational processing to achieve its mature form during ovarian development.

Hormonal Control of Yolk Protein Synthesis in Molluscs

Gonadotropin-releasing hormone (GnRH) has been established to have an essential role in reproduction in molluscs, as it does in that of vertebrate species; this topic has been reviewed extensively by Osada and Treen (2013). In cephalopods and gastropods, the presence of a GnRH-like peptide was initially demonstrated using heterologous antibodies, and the thus-identified GnRH was thereafter suggested to be involved in both behavioral and reproductive aspects. A role for GnRH in molluscan reproduction has now been confirmed for both bivalves and cephalopods, and such findings are expected to provide useful insights into the evolution of reproductive endocrinology.

In gastropods, the first study to suggest that a native molluscan GnRH-like peptide could be expressed in the molluscan nervous systems was carried out using the gastropod *Hellisoma trivolvis* and heterologous GnRH antibodies (Goldberg *et al.*, 1993). These authors speculated that the *Hellisoma* nervous system showed characteristics consistent with the existence of a GnRH-like peptide functionally similar to human GnRH. At that time, GnRH was assumed to be an example of convergent evolution that had occurred in parallel with the evolution of the vertebrate hypothalamic-pituitary-gonadal axis; therefore, the discovery of its existence in a gastropod was unexpected. Thereafter, research into the existence of molluscan GnRH-like peptides in gastropods has yielded reasonable success. For example, it was shown that GnRH-like neurons are present in the nervous systems of the freshwater snails *Helisoma* and *Lymnaea*, with a possible role for reproduction being hypothesized. The commercially important gastropod, the Pacific abalone, *Haliotis discus hannai*, was also found to possess GnRH-like peptides in the nervous system as well as in the ovary.

In bivalves, the first research that involved the indirect use of mollusc GnRH was performed in the late 1980s where it was shown that extracts from the cerebral ganglion and hemolymph of the blue mussel *M. edulis* were capable of promoting the incorporation of radiolabelled thymidine into the DNA of isolated mantle cells (Mathieu *et al.*, 1988), thereby promoting mitosis. It was therefore suggested that molluscan GnRHs may have a conserved structure that is found in other animal groups, but is not recognized by the vertebrate receptor due to differences in evolutionary lineage. In this way, the term “gonadotropin-releasing hormone” may be a bit inappropriate when used to discuss protostomian GnRH peptides, as gonadotropins have not been identified in protostomes, and protostome GnRH may not necessary stimulate gonadotropin release in vertebrates.

In cephalopods, a major breakthrough in molluscan GnRH studies came about when the full coding sequence of a GnRH peptide in the common octopus, *Octopus vulgaris* was identified (Iwakoshi *et al.*, 2002). This substance was referred to as “oct-GnRH-like peptide”, and the amino acid sequence of the mature peptide was confirmed by techniques such as nanoflow electrospray ionization time-of-flight mass spectrometry (nano-ESI-TOF-MS) analysis. It was also shown that this peptide at concentrations of 10^{-5} M was capable of significantly inducing the release of luteinizing hormone from anterior pituitary cells in birds (quail); this provided the most convincing confirmation thus far that peptides which had been found in octopus and other molluscan species were likely to be true GnRH peptides.

Introduction

The vertebrate testis produces spermatozoa and signalling molecules, such as sex steroid hormones and growth factors. These two functions are interconnected, since efficient sperm production depends, amongst others, on these locally produced signalling molecules which, however, also can have functions outside the testis. The process of sperm production, spermatogenesis, takes place in the spermatogenic tubules of the testes. The tubules contain two cell types, germ cells (in different stages of development) and Sertoli cells, a somatic cell type that is of crucial importance for facilitating the survival and development of germ cells during spermatogenesis. Germ and Sertoli cells together constitute the germinal epithelium. The wall of the spermatogenic tubules is formed by extracellular matrix material, connective tissue elements, and contains on the outside a layer of smooth muscle cells known as peritubular myoid cells. Between the spermatogenic tubules, we find the interstitial tissue with blood vessels, connective tissue and nervous elements, immune cells and, last but not least, the Leydig cells. These cells are the main source of the male sex steroids, androgens like testosterone, but also produce non-steroidal factors. Therefore, Leydig cells and their products are of great relevance for male fertility.

The endocrine system in vertebrates has evolved as a master control system over reproduction. Regulated by the brain, the pituitary produces two gonadotropic hormones, luteinizing hormone (LH) and follicle-stimulating hormone (FSH) that jointly control pubertal maturation and adult functioning of the testis. Sertoli cells express the receptor for FSH (FSHR), which is of course important for regulating Sertoli cell functions. LH, on the other hand, controls Leydig cell activities via the LH receptor (LHCGR), such as the production of androgens. The latter regulate testis functions via the androgen receptor (AR), which is expressed by Sertoli, peritubular myoid and Leydig cells, cell types expressing many genes critical for spermatogenesis. It appears that FSH and androgens are the two most important hormones regulating Sertoli cell activities, such as providing structural and metabolic support and regulatory input for the developing germ cells. Receptors for FSH and, in many species, receptors for androgens are not expressed by germ cells. Therefore, the endocrine control of spermatogenesis first targets the FSHR- and AR-expressing somatic cells, which then relay the endocrine input in a paracrine manner or by direct cell-cell contacts to the germ cells, which then respond by adapting their proliferation and differentiation behaviour. During spermioogenesis in fish, however, steroid receptor expression in spermatids may play a role (see [Section Regulation of Spermioogenesis by Steroids and Sertoli Cells Factors](#)).

Despite an overall similarity among different vertebrate groups, evolution has taken a somewhat different path in fish with respect to the biological activities of the gonadotropic hormones. The main point is that in fish, FSH has gained a strong steroidogenic potency because Leydig cells not only express the receptor for LH, as in all higher vertebrates, but also the receptor for FSH. Therefore, FSH alone can fulfil the functions, for which in mammals FSH and LH are required. It is therefore not surprising that genetic experiments with zebrafish showed that loss of LH, or of the LH receptor, did not compromise male fertility ([Chu et al., 2015](#); [Zhang et al., 2015](#)). Also remarkable in fish is the observation that the receptor for LH is expressed by germ cells toward the end of spermatogenesis (see [Section Regulation of Spermioogenesis by Gonadotropins](#)).

The Main Steps of Spermatogenesis

A population of spermatogonial stem cells (SSCs) forms the basis of the germ cell population. When dividing, an SSC can undergo a self-renewal division resulting in two single SSCs, or it can undergo a differentiating division to produce two spermatogonia as the first step of the development toward spermatozoa. After differentiating divisions, germ cells do not separate completely when dividing but remain connected by a cytoplasmic bridge, forming first a pair and then an elongating chain of interconnected cells. This is a typical feature of differentiating germ cell divisions in all animals. The balance between self-renewal and differentiating divisions is tightly regulated: Too much self-renewal limits the number of differentiating cells, reduces sperm production and might lead to germ line stem cell tumours, while too much differentiation exhausts the SSC reservoir, eventually leading to infertility.

When SSCs undergo a differentiating division and form a pair of spermatogonia connected by a cytoplasmic bridge, they have entered the process of spermatogenesis, which consists of three main phases: the mitotic, the meiotic and the spermioogenic

phase. During the mitotic phase of spermatogenesis, germ cells proceed through a series of consecutive mitotic cell cycles as an interconnected cell clone of first 2, then 4, 8, 16, etc. differentiating spermatogonia derived from a single SSC. Via the intercellular bridges, the members of a given clone synchronize their development. The number of mitotic cell cycles a germ cell clone undergoes is genetically determined, and therefore fixed in a given species but can differ in different species. It ranges between 6 and 14 (often 8) in different fish species (Schulz and Nóbrega, 2011). After completing the mitotic expansion, germ cells proceed sequentially through two highly conserved processes. The first one is known as meiosis and involves two special cell cycles. First, in primary spermatocytes, the maternal and paternal genetic information is recombined (cross-overs) in preparation of the 1st meiotic division. The secondary spermatocytes emerging from this division quickly divide again in the second meiotic division that is not preceded by DNA duplication. The spermatids emerging from the second meiotic division therefore possess a haploid set of (recombined) genes. Germ cell development is completed during spermiogenesis (see **Section Spermiogenesis and Its Regulation**). During all phases, the germ cells are enveloped by Sertoli cells and depend on their support for survival and progression through the different steps constituting spermatogenesis.

The Sertoli - Germ Cell Relation in Cystic Spermatogenesis

The close relationship between Sertoli and germ cells is seen in all vertebrates, but there is an important difference in the Sertoli-germ cell relation between fish and amphibians (anamniote vertebrates) on the one hand and reptiles, birds and mammals (amniote vertebrates) on the other hand.

In amniote vertebrates, Sertoli cells proliferate until puberty. Then tight junctions are formed between neighboring Sertoli cells and their proliferation stops. The tight junctions create in the spermatogenic tubule a separation into a basal compartment, where we find the spermatogonia, and an adluminal compartment, in which meiosis and spermiogenesis take place (**Fig. 1(A)**). This also secludes meiotic and spermiogenic cells from the immune system, which is not familiar with the surface structure of these later developmental stages. Hence, during amniote spermatogenesis, germ cells move from the basal to the adluminal compartment along the lateral surface of the Sertoli cells. In this way, Sertoli cells are arranged as a single layer of cells residing on the tubular wall, where they constitute a permanently present, no longer proliferating cell layer interconnected by tight junctions. Germ cells form a number of layers of progressively differentiated germ cell types that move from the basal to the adluminal compartment during development. Since consecutive waves of spermatogenesis produce germ cells that pass along the Sertoli cells from the basal to the adluminal compartment, any given Sertoli cell is in contact with germ cells in different stages of development (**Fig. 1(A)**), implying that they belong to different clones, most likely derived from different SSCs.

In the fish testis, spermatogenesis of course also starts with a single SSC, which is enveloped by 1 or 2 Sertoli cells. This combination of an SSC and the associated 1 or 2 Sertoli cells is the basic functional unit of the germinal epithelium in anamniote vertebrates and is referred to as a spermatogenic cyst. When the SSC differentiates and forms a clone of 2, 4, 8, etc. spermatogonia, the growing germ cell number in the cyst requires that also the cyst-forming Sertoli cells proliferate, thereby providing the increasing space required by the growing germ cell clone (**Fig. 1(B)**). This highlights two important differences compared to the Sertoli germ cell relation in amniote vertebrates: First, Sertoli cell proliferation needs to accompany developing spermatogenic cysts, rendering Sertoli cell proliferation a characteristic of the postpubertal, spermatogenic testis. Secondly, a given Sertoli cell usually is in contact with only one or two germ cell clones at a time (**Fig. 1(B)**) and accompanies these clones through the different stages of development until the cysts opens to release of spermatozoa. Hence, while an amniote Sertoli cell is rather “busy” with taking care of several different stages of developing germ cells and therefore shows regional differentiation and polarity, an anamniote Sertoli cell fulfils the same tasks sequentially, usually taking care of only one or two stages of germ cell development at a given time (Leal *et al.*, 2009; Schulz *et al.*, 2010).

Stem Cell Niche in the Fish Testis

Prolonged male fertility depends on maintaining a population of SSC. Tissue-specific stem cells need a distinctive microenvironment to retain their stemness, which is referred to as the stem cell niche. In the testis, somatic cells provide and determine the niche environment. Sertoli cells are important contributors to the niche environment but other somatic cells, such as the peritubular myoid cells, are relevant as well for determining the SSC self-renewal/differentiation balance. Moreover, signals arriving via the blood, can reach SSCs and other spermatogonia and contribute to the niche environment in the testis. In mice, SSCs are motile cells and can leave the niche, thereby becoming exposed to conditions that do not allow maintaining their stemness, i.e., the cells will differentiate and hence contribute to sperm production. The niche place they vacated by moving out, on the other hand, becomes available for a newly formed SSC (Lord and Oatley, 2017).

It is not known if SSCs in fishes and amphibians are motile cells. However, being enveloped by Sertoli cells in the cystic type of spermatogenesis, an SSC is likely to become apoptotic when moving away from the Sertoli cell support, unless this SSC – when leaving its supporting Sertoli cell – can recruit a vacant or idle Sertoli cell. Interestingly, one of the earliest signs of pubertal or seasonal testis growth in salmonid fish is an increased proliferation activity of Sertoli cells, leading to an accumulation of vacant Sertoli cells (**Fig. 2**). Assuming that these vacant Sertoli cells produce signals tipping the balance in favour of self-renewal

Fig. 1 Comparison of mammalian (A, mouse) and fish (B, zebrafish) testis. Segments of spermatogenic tubules are shown to illustrate the differences in Sertoli/germ cell relation between non-cystic (A) and cystic (B) spermatogenesis. The germinal epithelium contains Sertoli (SE) and germ cells, delineated by a basal lamina (BL) and peritubular myoid cells (MY). Also interstitial Leydig cells (LE) and blood vessels (BV) are shown. (A) spermatogonia (SG); spermatocyte (SC); round spermatid (RST); and elongated spermatid (EST). (B) Type A undifferentiated* spermatogonia (A_{und*}) (stem cell?); type A undifferentiated spermatogonia (A_{und}); type A differentiating spermatogonia (A_{diff}); type B spermatogonia (B (early-late)); leptotenic/zygotenic primary spermatocytes (L/Z); pachytenic primary spermatocytes (P); diplotenic spermatocytes/metaphase I (D/MI); secondary spermatocytes/metaphase II (S/MII); early (E1), intermediate (E2) and final spermatids (E3); spermatozoa (SZ). Reproduced from Schulz, R.W., de França, L.R., Lareyre, J.J., *et al.*, 2010. Spermatogenesis in fish. *General and Comparative Endocrinology* 165, 390–411.

divisions, newly formed SSCs would then associate with vacant Sertoli cells to form new spermatogenic cysts. This type of Sertoli cell proliferation seems the prerequisite to increase the SSC niche space in the testis, such that the testis becomes populated by the starting units of cystic spermatogenesis. In cystic spermatogenesis, each wave of spermatogenesis requires the production of new cysts and the associated Sertoli cell proliferation. The development of existing cysts also involves Sertoli cell proliferation. Therefore, a Sertoli cell progenitor population may be present in the testis of anamniote vertebrates but still needs to be demonstrated (França *et al.*, 2015).

In many species of fish (e.g., salmonid and cyprinid fish), these starting units of spermatogenesis (i.e., 1 or 2 Sertoli cells enveloping a single type A spermatogonium) are randomly distributed in the germinal epithelium of the testis, which is referred to as the unrestricted spermatogonial distribution. In fish species showing the restricted spermatogonial distribution, on the

Fig. 2 Sertoli cell groups in Atlantic salmon testis at the beginning of the seasonal testis growth phase. (A) Squares (1,2) show several Sertoli cells, indicated by numbered Sertoli cell nuclei that are grouped around a single type A undifferentiated spermatogonium (A_{und}). Areas delineated by dashed lines (e.g., 3) show Sertoli cells apparently not (yet) in contact with germ cells (possibly containing Sertoli cell progenitor cells). Staining: Hematoxylin and eosin. (B) Immunocytochemical detection of a proliferation marker (phosphorylated histone H3 (pH3)) on another section of the same testis shown in A. pH3-positive Sertoli cell nuclei (arrowheads) indicate proliferation of Sertoli cells at the beginning of testis growth. The square highlights several Sertoli cells (SC1-SC5) that are already associated with a single spermatogonium type A_{und} . Sertoli cells continue proliferating, potentially providing niche space for new, single type A_{und} spermatogonia (cyst formation). Double asterisks indicate pH3-positive single type A_{und} spermatogonia. Reproduced from França, L.R., Nóbrega, R.H., Morais, R.D.V.S., de Castro Assis, L.H., Schulz, R.W., 2015. Sertoli cell structure and function in anamniote vertebrates. In: Griswold, M.D. (Ed.), *Sertoli Cell Biology*. Amsterdam: Elsevier, pp. 385–408.

other hand, the intratesticular location of stem cell cysts is non-random and becomes predictable. Stem cells are located in the periphery of the testis, close to the organ wall (tunica albuginea). Newly formed cysts that started differentiation are displaced along the spermatogenic tubule toward the central collecting duct. Hence, in these species, the developing cysts is moving centrally while progressing through spermatogenesis and then opens to release sperm into the collecting duct. This spatial arrangement is found in evolved taxonomic groups, such as silversides and toothcarps. Also an intermediate type exists, in which undifferentiated spermatogonia show a preferential but not exclusive localization close to the testicular periphery. This is found in some perch- or cod-like fish or in flatfish species.

Regulation of the Mitotic and Meiotic Phases

In this section, we will discuss aspects of the endocrine and paracrine regulation of the mitotic and meiotic phases. The overall dependency of spermatogenesis on regulatory input by the pituitary has been demonstrated already 30 years ago by surgical experiments removing the pituitary followed by gonadotropin replacement studies (Khan *et al.*, 1987). More recently, genetic experiments in zebrafish (Chu *et al.*, 2015; Zhang *et al.*, 2015) involving loss-of-function of the gonadotropins, FSH and LH, or of their receptors (FSHR and LHCGR), confirmed that spermatogenesis is not possible without gonadotropin signalling.

Incubating eel testis in a primary tissue culture system demonstrated that androgen treatment alone induced complete spermatogenesis and sperm production (Miura *et al.*, 1991). On the other hand, FSH was able to stimulate the differentiating proliferation of spermatogonia and their entry into meiosis in a steroid-independent manner in studies using zebrafish testis in a similar primary tissue culture system (Crespo *et al.*, 2016). This data suggests that FSH (or LH) exerts stimulatory effects on spermatogenesis involving sex steroid production but that FSH has in addition direct stimulatory effects not depending on a functioning steroidogenic system, probably mediated by the FSH receptor expressing somatic cells, which are in fish Sertoli and Leydig cells.

Steroid-regulated effects in fish involve oestrogen-mediated stimulation of SSC self-renewal, androgen-mediated effects on testicular gene expression, the latter identifying the importance of a growth factor belonging to the TGF β family, anti-Müllerian hormone (AMH) that blocks SSC differentiation and needs to be down-regulated (by androgen or FSH, depending on the fish species) to facilitate the initiation of spermatogenesis (Schulz *et al.*, 2010). Finally, also progesterone-mediated effects were identified in a number of species, stimulating progression through the later spermatogonial generations and entry into meiosis. Hence, all three types of sex steroids have specific effects on spermatogenesis in fish. Androgens have the widest range of effects since they stimulated the complete development from SSC differentiation to sperm production. On the other hand, recent genetic experiments in zebrafish show that spermatogenesis still proceeds normally when oestrogen production was blocked (Dranow *et al.*, 2016), or when nuclear progesterone receptors were not functional (Zhu *et al.*, 2015), suggesting that progesterone and oestrogen-mediated regulation is not of crucial relevance, at least for zebrafish spermatogenesis.

Fsh-induced, steroid-independent effects on testicular gene expression were examined in rainbow trout (Sambrovi *et al.*, 2013) and zebrafish (Crespo *et al.*, 2016). These studies identified a few hundred genes differentially expressed in response to FSH. Follow-up work on some of the most interesting candidate genes in zebrafish has shown that the stimulatory effects of FSH were mediated by down-regulating inhibitory factors (e.g., AMH) and by up-regulating stimulatory factors. The latter category contained growth factors produced by Leydig cells (insulin-like peptide 3, INSL3) or by Sertoli cells (insulin-like growth factor 3, IGF3) that then mediate the FSH effects to alter germ cell development. Future work will probably reveal the roles of more factors that have already been identified as regulated by reproductive hormones but where specific functions have not been characterized yet; many of these signalling systems are known from other physiological functions but also operate in the testis, such as the hedgehog and Wnt signalling systems best known for their roles in embryonic development and cancer.

What events in spermatogenesis are regulated by the different signalling systems mentioned so far? We have seen earlier that the number of mitotic cell cycles is genetically determined; also meiosis and spermiogenesis are conserved, genetically fixed processes. Therefore, modulating the quantity of sperm production seems limited to regulating how many starting units, i.e., cysts consisting of a single spermatogonium enveloped by one or two Sertoli cells, enter the process of spermatogenesis. Entering this differentiation process in fact reflects that a decision has been taken by such a starting unit, namely the decision regarding the question if the upcoming cell division should be a self-renewal, or a differentiating division. Before that, one other decision needs to be taken: should the starting unit show any proliferative activity at all or not, i.e., remain quiescent or become recruited into cell cycling? This is a question of the timing of proliferation activity.

Up until puberty, testis tissue in fish grows slowly in a so-called allometric manner (i.e., the growth speed of the testis is similar to the growth speed of the rest of the body). However, with puberty, a superallometric growth phase starts, reflecting the start of spermatogenic activity. This requires a change in the regulatory input, so that the slow self-renewal of SSCs in immature males is first changed to accelerated self-renewal and then to differentiation. In many seasonally reproducing species, testis tissue goes through a rapid growth phase, reaches the peak weight and then shows a certain weight loss toward the spawning season, since new cyst formation stops while existing cysts continue to develop through spermiogenesis to sperm, which is associated with a reduction in cellular mass and an overall weight loss (see **Section Spermiogenesis and Its Regulation**). After the spawning season, residual sperm is resorbed and testis weight decreases back to low starting levels. These repeated growth/shrinkage cycles in consecutive reproductive seasons require that first new spermatogenic cysts are formed, which then start differentiating while more cysts keep being formed. At a certain point in time, when maximum testis size has been reached, the production of new cysts ceases, and all cysts mature such that the fully mature testis contains only sperm and a few quiescent SSCs, representing the stem cell reserve for the next cycle. With respect to the production of new spermatogenic cysts, the conclusion is that their production is initiated at the beginning of puberty or a subsequent reproductive cycle and continues until the signals promoting cyst production cease. From then on, the existing cysts keep differentiating while no new ones are added, so that after some time, all cysts have spermiated and the testis is filled with sperm. Based on the present knowledge, we assume that FSH plays a decisive role in this regard, both with respect to the start as well as to the stop of cyst production. Environmental conditions (e.g., water temperature, photoperiod, food availability, behaviour of conspecifics etc., the significance of a specific set of parameter depending on the reproductive biology of the species in question) regulate changes in FSH release via the brain-pituitary axis, thereby timing the FSH release according to maximise the reproductive success of a given species.

The final point to consider here is apoptosis as factor modulating the germ cell production efficiency. Part of the germ cells undergoing normal spermatogenesis are lost to apoptosis (Shaha *et al.*, 2010). The apoptotic loss of 30%–70% of germ cells is the physiological range found in different species. It is important to realize that this loss is not reflecting toxicological insults or pathological conditions but simply the fact that spermatogenesis is a process producing very many cells in a short time (e.g., in humans ~1500 sperm cells per heartbeat). Under these conditions, it is inevitable that mistakes occur in some of the germ cells, often during DNA replication or DNA repair processes. If these errors cannot be repaired in time, apoptosis is activated in the defective cell at the next cell cycle check point. Also for this aspect, FSH and androgens are important to limit the apoptotic loss

Fig. 3 A–D: Schematic drawing of steps of spermatid type I differentiation occurring within seminiferous tubule. (A) Early spermatid shows a spherical nucleus containing diffuse homogeneous chromatin (blue) and a forming centriolar complex medial to nucleus (green). Cytoplasmic bridges are linking two spermatids together. (B) Round spermatid is initiating chromatin condensation. The primordial nuclear fossa arise inside the nuclei where the forming centriolar complex is locating. The cytoplasm (grey), containing mitochondria (red) is reduced around the nucleus. (C) Intermediate spermatid shows advanced chromatin condensation and the perpendicular formation of the flagellum from the centriole. The cytoplasm is forming the middle piece along the developing flagellum and is reducing with the appearance of vacuoles (white). (D) Late spermatid shows highly condensed chromatin within the nucleus, a longer flagellum and a very reduced cytoplasm. Mitochondria moved to the mid piece, where they eventually fuse. E–G: Alternative types of spermatids. (E) In type II spermiogenesis, the flagellum develops parallel to the nucleus without nuclear rotation. (F) In type III spermiogenesis, the flagellum forms centrally without nuclear rotation. (G) In some teleost fish species, the nucleus is elongated at the final step of spermiogenesis.

of germ cells (O'Shaughnessy, 2014), by regulating Sertoli cell functions such that they can optimally support germ cells, thereby reducing apoptotic loss to the inevitable minimum.

Spermiogenesis and Its Regulation

Three types of spermiogenesis were described in fish and this classification is based on the orientation of the flagellum with respect to the nucleus (Wootton and Smith, 2014). Also, based on the progressive condensation of the nucleus, three stages of spermatid development were described (Fig. 3; Kunz-Ramsay, 2013). The process of spermiogenesis seems to be relatively short in teleost fish where it takes 2–7 days. However, the timing has been studied in not even a handful of species so far and more comparative data is required.

When spermatids have developed into fully differentiated spermatozoa, the cytoplasmic bridges that connected germ cells during their development are broken and the germ cells are individualized. Spermatozoa are released from the spermatogenic cyst into the lumen of the spermatogenic tubule by opening the junctional complex that connect neighboring Sertoli cells forming the wall of a spermatogenic cyst. This process is known as spermiation (O'Donnell *et al.*, 2011). Notably, in some teleost species (e.g., in certain flatfish species), spermatogenesis is semicystic, i.e., round spermatids from different germ cell clones are released into the lumen of spermatogenic tubules, where they complete spermiogenesis (Uribe *et al.*, 2014). In yet other species (e.g., in some live bearing tooth-carps), spermatozoa are not released into the lumen directly but Sertoli cells form a packaging capsule around spermatozoa, called spermatophores. For most teleost fish, spermiogenesis does not involve spermatid elongation, although it is common in the semicystic spermatogenesis (Fig. 3(G); Schulz *et al.*, 2010).

Molecular Regulation of Gene Expression in Spermatids

The molecular regulation of spermiogenesis in teleost fish is largely unknown. However, it appears that the nuclear condensation in spermatids involves acetylation and then displacement of histones from the nucleus and their replacement by transition proteins and protamines, similar to what has been described in mammals. In a context of extreme chromatin condensation, little transcription occurs in spermatids. Indeed, mRNAs transcribed earlier are stored often bound to RNA-binding proteins that also serve to distribute the required mRNAs via the intercellular cytoplasmic bridges. Nonetheless, the differentiation of round spermatids into spermatozoa requires the transcriptional activation of some post-meiotic genes, among them the genes encoding spermatid maturation factors and spermatozoa-specific proteins involved in flagellum formation. In mammals, this occurs in spermatids and depends on an intracellular cAMP rise and the expression of the cAMP responsive element modulator (CREM), that binds cAMP responsive *cis* elements in the promoter of target genes. However, the primary signals to activate this pathway in teleost germ cells is yet unknown.

Regulation of Spermiogenesis by Gonadotropins

The cellular differentiation steps occurring during spermiogenesis are regulated primarily by gonadotropins and/or sex steroids in mammals and fish (Uribe *et al.*, 2014). Although FSH does not appear to be necessary for spermatozoa formation itself, as neither disruption of FSH nor of the FSHR compromised fertility in male zebrafish, FSH is potentially an indirect signal to induce cAMP increases and the association of CREM with its activator (ACT) through a paracrine circuit operating between germ and Sertoli cells in mice. However, it is also possible that LH compensates the experimental lack of FSH in zebrafish, since in most teleost fish, high concentrations of LH can activate the FSHR. Indeed, loss of both, the FSHR and the LHCGR resulted in infertile zebrafish males, while loss of LH alone had no effect on fertility. In mammals, on the other hand, LH is crucial for fertility since in LHCGR (or LH) knockout mice, serum T levels are reduced and spermatogenesis is arrested at the round spermatid stage, leading to the total absence of spermatozoa. Also, LH-mediated T release by Leydig cells plays a crucial role in spermiogenesis since this androgen can fully restore spermiogenesis in LHCGR-null mice. However, this is not the case in humans, where T alone is insufficient to induce progression of spermatids through spermiogenesis *in vitro*. It is possible that the LH/LHCGR pathway plays an additional role in spermiogenesis independent of androgen production. This would require expression of the LHCGR by germ cells. Interestingly, in fish the LHCGR was found either in spermatocytes or round spermatids (Chauvigné *et al.*, 2014; Fig. 4). In Senegalese sole, treatment with LH promoted the differentiation of spermatids into spermatozoa *in vitro* after 3 days of incubation. LH also initiated the transcription of genes potentially involved in flagellum formation and protein ubiquitination through a cAMP/PKA-dependent signalling pathway. This corroborates the fact that in testis many genes belonging to the germ cell line are regulated, either indirectly or directly, by LH in trout or sole. However, whether LH directly activates gene transcription through a CREM-like factor in teleost spermatids or via one of the several other mediators found in different studies remains to be studied (Fig. 4).

Regulation of Spermiogenesis by Steroids and Sertoli Cells Factors

In Senegalese sole, androgens had no effect on the differentiation of spermatids *in vitro*. However, a role of these steroids during earlier stages of spermatid formation/differentiation cannot be ruled out because in this species, spermatocytes and spermatids

Fig. 4 Schematic drawing of potential endocrine regulation of spermiogenesis in teleost fish. Spermatids, enclosed in Sertoli cells, are subjected to different hormonal signals. Besides the store RNA, genes necessary for flagellum formation are transcribed *de novo* under the regulation of various transcription factors (TF), potentially dependent on cAMP pathway. LH from the circulation activates directly LHR in spermatid to drive spermiogenesis in a cAMP-dependent manner. Also, it activates steroidogenesis in Leydig cells. Steroids like androgens or progestins could activate their receptors (SR) in spermatid. Spermatid potentially can synthesize steroids also, which would create a regulatory loop. Finally, FSH activates its receptor in Sertoli that secrete growth factors (GF), that could activate their receptors (GFR) in spermatids to regulate spermiogenesis.

express androgen receptors (Fig. 4). In Sole and others species, the progesterone receptor was found in late germ cells and thus, progestins may have effects on spermiogenesis additionally to their well-known activation of spermiation. Also, in different fish species steroid-producing enzymes are present in germ cells which suggest that an autocrine regulation of spermatid differentiation could occur by steroids (Fig. 4). Finally, other factors may be necessary to support spermiogenesis, such as paracrine factors secreted by Sertoli cells such as insulin-like growth factors or trypsinogens (Fig. 4; Schulz *et al.*, 2010). The specific role of these endocrine mediators remains to be further investigated.

Introduction

Elasmobranchs, comprising skates, rays and sharks, belong to chondrichthyans which include also the chimaeras (Holocephalans). Chondrichthyans are the sister group of bony vertebrates with a time of divergence estimated between 462 and 421 million years ago (MYA) and recent knowledge on fossilized chondrichthyans suggest that the last common ancestor of elasmobranchs and holocephalans lived about 370–380 MYA. Despite the phylogenetic interest of chondrichthyans and their high number of species (around 1200), they have been the subject of too few publications, notably concerning their reproduction. However, spermatogenesis in elasmobranchs is at the origin of old observations, particularly at the middle of the 19th century with the advent of microscopy, because of the advantages associated to the anatomical organization of their testis. In 1841, Lallemand observed that spermatozoa formation occurs into “spherical ampullae”, what we name presently spermatocysts, in rays and, in 1875, Semper gave a first description of the different stages of spermatogenesis in dogfish. [La Valette St George \(1878\)](#) was the first to describe the close association between germ cells and Sertoli cells to give, what he called “spermatogennum”, currently called “spermatoblast”. A century later, the stages of spermatogenesis were more precisely classified and quantified by works of [Mellinger \(1965\)](#), [Stanley \(1966\)](#) or [Holstein \(1969\)](#) in the lesser spotted dogfish *Scyliorhinus canicula* (Carcharhiniformes) and the spiny dogfish *Squalus acanthias* (Squaliformes). For all elasmobranchs, the unit structure of the testis is the spheroidal spermatocyst (cyst) (terms used by previous authors were ampulla or follicle), defining their testicular structure as polyspermatocystic type. Each cyst is made up of spermatoblasts in which one Sertoli cell is associated to a clone of synchronous developing germ cell, from 1 spermatogonium initially to 64 mature spermatids. Cysts originate from the germinative zone located at fixed sites on the dorsal or dorsal-lateral margins of the testis according to species. Because new cysts are being formed and added continually, older cysts are moved in sequential order leading to a zonate arrangement according to the spermatogenetic wave. Therefore, a cross section of the testis displays a dorsoventrally oriented succession of zones corresponding to spermatogonial, spermatocytes, early spermatids, late spermatids and degeneration zones.

The Male Genital Tract

Anatomically, the male genital tract of elasmobranchs is elaborated ([Fig. 1](#)). Two elongated testes have the particularity to be closely associated to the epigonal tissue, a lymphomyeloid tissue producing leukocytes, granulocytes and lymphocytes. Spermatozoa are collected through a paired duct system associated to each testis and made of intra-testicular tubules (branched and stem tubules),

Fig. 1 Illustration of the male genital tract in *Scyliorhinus canicula*.

collecting tubules and from two to six efferent ducts (*rete testis* homolog) in sharks or one efferent duct in rays and skates. Efferent duct is followed by one epididymis composed of a proximal and distal segment, one deferent duct enlarged at its end into seminal vesicle. Seminal vesicle often expanded to form an ampulla used for sperm storage and the two seminal vesicles converge in their posterior region. In skate and rays, Marshall's alkaline glands (incorrectly named sperm sacs since they are devoid of sperm) arise as diverticula from this posterior region. Sperm passes from the urogenital sinus to the urogenital papilla which consists of the groove of pelvic clasper, the copulatory organs of chondrichthyans used for internal fertilization. Male elasmobranchs possess unique reproductive associated glands: the Leydig's gland and siphon sacs in sharks or clasper glands in skates and rays. Leydig's gland is closely associated and connected to the deferent duct and secretes part of the seminal fluid. Since their functions remain to be clarified, siphon sacs could either facilitate the transfer of sperm to the female (Gilbert and Heath, 1972) by inducing uterine contractions or assist sperm competition by washing female genital tract before ejaculation with a water flux. Most skates and rays have a clasper gland that may facilitate copulation by providing a lubricant and a fluid coagulating with sea water that could seal the groove of the clasper to form a tube (Wourms, 1977). A diversity of functions could be respectively attributed to siphon sacs and clasper glands but both, in terms, facilitate fertilization.

Anatomy of Testis

According to species and testicular type, germinative area is unique or multiple. In Squalomorph, Galeomorph and Carcharhinidae shark species, the germinative area consists of one band located between albuginea and the main testicular blood vessel which runs the dorsal length of the testis. This testicular structure has been classified as diametric-type testis (Pratt, 1988) (Fig. 2). Squaliformes as *Centroscyms coelolepes* and *Centrophorus squamosus* may present lobate testis and each lobe has a diametric structure (Girard et al., 2000). In Lamniformes, testis comprises seminiferous lobules (Radial-type testis). The germinative area is in the center of each seminiferous lobule and cyst development proceeds radially from the germinal area. In skates and rays, testis combines radial and diametric structure and was termed "compound" by Pratt. Their testis may comprise lobate divisions as observed for the Cownose Ray, *Rhinoptera bonasus* (Poulakis and Grier, 2014). Germinative areas originate from the germinal papilla that appears as a small projection at the dorsal surface of the testis and cyst development proceeds diametrically from each germinative area.

The Mitotic Proliferative Phase of Spermatogenesis

To describe precisely the different stages of spermatogenesis, the example of *Scyliorhinus canicula* will be detailed below (Loir et al., 1995) (Fig. 3). Stage I corresponds to large spermatogonia (10 µm in nuclear diameter) of the germinative zone, surrounded by elongated somatic cells which correspond to Sertoli cell precursors. In the different subparts of the germinative zone, from the area just behind the fibrous albuginea toward the blood vessel, spermatogonia are isolated, paired or in clusters of 4 and they can be qualified of A single (As), A paired (Apr) and A und4 undifferentiated spermatogonia, respectively. Their ultrastructure observed by transmission electron microscopy reveals a nucleus with chromatin of a mottled appearance, a nucleolus and a cytoplasm containing numerous mitochondria and a dense material, the germinative nuage. From the first mitotic division, all spermatogonia will be connected with intercellular bridges to form a germ cell syncytium (Fig. 4). While leaving the germinative area, both Sertoli cell precursors and spermatogonia proliferate and both types of cells regroup progressively to form spherical cysts with a lumen that progressively appears (stage II). Stage III corresponds to the end of the cyst formation with a single layer of Sertoli cell nuclei around the central lumen and a single layer (stage IIIa) or two layers (stage IIIb) of spermatogonia toward the basal lamina. Here, it is important to notice that the cyst formation (stage IIIa) coincides with the end of Sertoli cell divisions and to the further four mitoses of differentiated spermatogonia (stages IIIb to VI). Stage IV has four layers of spermatogonia and Sertoli cell nuclei remaining at the adluminal position. Stage V presents five layers of spermatogonia and the Sertoli cell nuclei are at an adluminal (majority) or at an intermediate position. Stage VI exhibits about six layers of spermatogonia (corresponding to pre-leptotene spermatocytes) and Sertoli cell nuclei are in an intermediate (majority) or basal position. The number of germ cells per spermatoblast is 4, 8 and 16 for stages IV, V and VI, respectively.

Considering the ratio number of 1 Sertoli for 1 spermatogonium at stage IIIa, and the number of Sertoli cell nuclei per cyst (reflecting also the number of spermatoblasts per cyst), it is possible to evaluate the number of cell mitotic divisions for undifferentiated spermatogonia. Holstein (1969) has determined 469 spermatoblasts per cysts in *Squalus acanthias* and this number is about 500 in *Scyliorhinus canicula* cysts (Stanley, 1966) and about 250 in *Torpedo marmorata* cysts (Wourms, 1977). In *S. canicula* and *S. acanthias*, this will correspond to 9 cell cycle divisions for undifferentiated spermatogonia (from As to Aund 512) and to 4 more divisions for differentiated spermatogonia (from Ad1 to PL spermatocytes), considering that no division occurs between the last stage of undifferentiated spermatogonia and the first stage of differentiated ones. Concerning *T. marmorata*, the total number of spermatogonial mitotic divisions is 12 instead of 13. This high proliferative phase allows to produce a large number of spermatozoa from a small number of germinal stem cells. Otherwise, the difference between the theoretical (512) and observed (469) number of spermatoblasts suggests an apoptosis control of testicular homeostasis as observed for all vertebrates and studied in the shark *S. acanthias* (McClusky, 2012) or in the ray *T. marmorata*.

This ability to observe these different generations of spermatogonia is also of interest for studying spermatogonial stem cells and their progeny by establishing a molecular signature for each of them using *in situ* hybridization and immunocytochemistry

Fig. 2 Anatomy of testis. Adapted from Pratt, H.L., 1988. Elasmobranch gonad structure: A description and survey. Copeia 3, 719–729.

approaches. Such studies have shown, for example, that one of the most universal spermatogonial stem cell regulator, the GDNF family receptor GFRa1, is expressed in undifferentiated spermatogonia (Bosseboeuf *et al.*, 2014; Gautier *et al.*, 2014).

Meiosis

In the dogfish *S. canicula*, meiosis proceeds from stages VII to XI (Fig. 3). Stage VII corresponds to cysts containing the primary spermatocytes at the meiotic prophase and all the Sertoli cell nuclei are observed against the basal lamina. Stage VIII corresponds to the first meiotic division (metaphase, anaphase, telophase) which gives secondary spermatocytes (stages IX and X). At the end of meiosis, the number of early spermatids (or round spermatids) is of 64 per spermatoblast (stage XI).

Fig. 3 Stages of spermatogenesis in *Scyliorhinus canicula*. Associations between Sertoli cells (in blue) and germ cells (in yellow or black) are illustrated during stages of spermatogenesis (I to XVIII). Schemes of the evolution of a single spermatoblast in cysts containing spermatogonia (IIIa to VI), spermatocytes (VII, IX), spermatids (XI–XVIII) are represented in the lower part of the figure. Corresponding histology is in the upper part of the figure. I–II: germinative and transition zones.

Spermiogenesis

Spermiogenesis is the development of spermatids into mature spermatozoa. During this process, the main cell transformations are the acrosome formation, the compaction of chromatin with the replacement of histones by transition proteins and then protamines, the flagella assembly and the cytoplasm reorganization with elimination of its major part and of its organelles to keep a cytoplasm mainly restricted to the midpiece containing mitochondria. In *S. canicula*, stage XI corresponds to cysts with young round spermatids arranged as “a festoon figure” with nuclei showing patches of dense chromatin and flagella which are noticeable (Fig. 3). In stage XII, condensation of the chromatin is well advanced and elongation of the spermatid head, a characteristic feature of chondrichthyan spermatozoa, occurs and is completed at stage XIV. At this stage spermatids are arranged in parallel bundles which are perpendicular to the basal lamina of the cyst. The helical twisting of the spermatid which includes the head, the midpiece and flagellar elements (the axoneme and/or microtubules according to species) has a function in spermatozoa motility achieved by revolving around their long axis. During stages XV to XVII, the nuclei of Sertoli cell migration towards the intermediate cytoplasm of the cell and spermatid bundles become more compact and close to the basal lamina. The midpiece of spermatid is also well noticeable at the back of the head. At the ultrastructure level, for the spiny dogfish, glycogen granules are present and dispersed between mitochondria, the acrosome forms an elongated cap over the nucleus of the spermatid and a short perforatorium develops between the nucleus and the acrosome (in the subacrosomal space) (Pudney, 1995). Classically, the function of the perforatorium is the penetration of the sperm through the egg chorion during fertilization. The flagellar apparatus of spermatozoa is also characterized by the presence of flagellar roots which form the axis of the midpiece and the existence of two longitudinal columns associated with the axoneme. The function of this longitudinal columns is unknown and could be associated to the revolving motility of spermatozoa by restringing lateral beating of the flagella.

Another characteristic feature during the stages of spermiogenesis in elasmobranchs, is the apparition of a large protein body in the intermediate cytoplasm of Sertoli cell (stage XVI), the Semper's body. Its function is unclear and it will be released with bundles of spermatozoa during spermiation. A similar body have been found in the semen of the spiny dogfish and named “Sertoli cell cytoplasm”. As it contains organelles (mitochondria, ribosomes, endoplasmic reticulum) and lipid droplets, some of them associated to steroid synthesis, Pudney and Callard hypothesized that it could contribute to the steroids found in the semen and necessary for maturation and maintenance of spermatozoa in the reproductive ducts (Pudney and Callard, 1986). Another hypothesis may be that the Semper's body is equivalent to the residual body observed for mammalian spermatids. Its function remains to be studied.

Fig. 4 Ultrastructure of spermatogonia associated to Sertoli cells at stage II. Intercellular bridges between spermatogonia (SPG) are indicated by arrows. S: Sertoli cell.

Stage XVIII corresponds to the spermiation which takes place by the detachment of the spermatid bundle which carries with him the adluminal part of the sertolien cytoplasm. Bundles of spermatozoa are then evacuated through the cystic collecting ductule (branched tubules), previously closed by a cellular plug. By taking into account the number of 500 spermatoblasts in *S. canicula* and of 250 in *T. marmorata*, it could be calculated that 32,000 and 16,000 spermatozoa will be produced per cyst, respectively for these species.

The post-spermiation cyst contains the remaining basal cytoplasm and nuclei of Sertoli cells and will be resorbed in the epigonal organ, underlying this characteristic feature of the close association between this lymphomyeloid tissue and the testis in elasmobranchs. Another interesting feature about this association was the inhibitory effect on DNA synthesis of premeiotic cysts by epigonal cytosolic extracts, suggesting a crosstalk between the two organs to regulate the spermatogenic cycle. Involvement of growth factors (GDNF, IGF1, bFGF...) and cytokines (IL1, G-CSF...) in the regulation of spermatogonial proliferation is now well documented in several species.

Blood-Testis Barrier

In amniotes, the blood-testis barrier (BTB) is essential for spermatogenesis and takes place during puberty when Sertoli cells stop mitosis. Classically, blood-tissue barriers restrict or control the entry of molecules present in circulation from entering a tissue or compartment. This barrier partially made of specialized junctions between Sertoli cells "protects" haploid cells in a specific micro-environment and allows also the production of the testicular fluid useful, in particular, for transporting spermatozoa. This blood-testis barrier can be visualized by exclusion of a high molecular weight (10 kDa) fluorescent dye. Using this approach, McClusky has shown that living post-meiotic cysts are impermeant, suggesting a functional blood-testis barrier in cysts containing spermatids in the spiny dogfish (McClusky, 2006). Furthermore, in spermatid cysts, tight junctions have been observed between Sertoli cells, reinforcing the presence of a BTB but the precise description of its ultrastructural components remains to be done.

Sperm Transport, Maturation and Storage

Structure of a branching intratesticular network of ducts has been well described in the starspotted smooth-hound *Mustelus manazo* (Park *et al.*, 2013). This system is composed of branched tubules, linked to cysts, which are connected via a secondary network of

stem tubules to the collecting tubules. Branched and stem ducts can be observed early in the cyst-forming area (stage II) and during the spermatogenic wave, cysts are still attached to branched tubules. This implies that both cyst and tubules will move together from the germinal to the mature zone of the testis, undoubtedly involving regulatory mechanisms not yet known. During spermiation, branched tubules open at their junction with the cyst allowing the flow of bundles of spermatozoa into the stem tubules. Transport of spermatozoa will be achieved thanks to the presence of ciliated epithelial cells lining the lumen of branched, stem and collecting ducts. Contraction of myoid cells surrounding the intratesticular ducts probably also contributes to the transport of spermatozoa towards the epididymis where maturation occurs. In mammals, spermatozoa acquire their motility and fertilizing properties during their epididymal transit. Epididymis has been poorly studied in elasmobranchs, which is surprising considering its size and its apparent similarity to that of mammals. Studies in the Port Jackson Shark, *Heterodontus portusjacksoni* and in the Clearnose Skate *Raja eglanteria* have shown that epididymis effectively participates in luminal fluid modifications, including sodium resorption, and that spermatozoa, immotile in the proximal segment, acquired their motility during their transit in the terminal segment of epididymis. In *Raja eglanteria*, the glycosylation activity of the Leydig's gland, connected to epididymis and to the deferent duct, is rather associated to spermatozoa aggregation. During their transport from the cyst, where they were aggregated into bundles, to the posterior segment of epididymis, bundles of spermatozoa are dissociated and spermatozoa reaggregate into the seminal vesicle where they are embedded in a mucoid matrix. Two basic types of spermatozoa aggregation are described for elasmobranchs: spermatozeugmata and spermatophores. In spermatophores, bundles of spermatozoa are embedded in a matrix with the heads inside and the flagella projected out the matrix. Spermatophores are found in Alopidae, Odontaspidae and Lamnidae. Spermatozeugmata are un-encapsulated masses of naked spermatozoa. Spermatozeugmata may consist of different architectures: simple aligned bundles of spermatozoa (*Squalus acanthias*, *Hydrolagus coliei*); radially aligned bundles of spermatozoa (*Charcharinus plumbeus*); several layers of sperm bundles (*Sphyrna lewini*).

Seasonality of Spermatogenesis

Spermatogenesis can show little or no seasonal changes in Elasmobranchs, as this is the case for *S. canicula* or the ray *T. marmorata* showing continuous spermatogenesis throughout the year. But in the spiny dogfish *S. acanthias*, caught along the United States Atlantic coast, the spermatogenic cycle is interrupted by germ cell apoptosis at the mitosis–meiosis transition in April–May, leading to a zone of degeneration. By studying this zone of degeneration, several information of interest can be found. Firstly, because this interruption is temporary, the resumption of the mitosis–meiosis transition will give new cysts that will lead to a displacement of the zone of degeneration (ZD) towards the mature side of the testis. So, the observation of this zone of degeneration along the time will give an idea of the duration of spermatogenesis. In the spiny dogfish, [McClusky \(2006\)](#) has thus established that the spermatogenic cycle spans about 2 years and that the duration from the Preleptotene stage to the more mature spermatid stage is of 9–10 months, underlining the long time required for spermatogenesis in that shark. In terms of sperm production, the displacement of the ZD at the mature side of the testis will lead to the absence of mature cysts and consequently the decrease of sperm production 9–10 months later, in February–March of the following year. Conversely, the higher number of cysts containing mature spermatids is observed between October and January and coincides with the matting period (December to February). Secondly, this zone of degeneration was experimentally reproduced in the dogfish *S. canicula* by partial hypophysectomy coupled with an increase of temperature starvation, suggesting that this mitotic–meiosis transition is a critical stage of spermatogenesis under gonadotrophin and environmental control. Consequently, seasonality of reproduction can be more marked to species that inhabit regions where environmental conditions vary widely with season.

A ZD has also been observed in the blue shark *Prionace glauca*, the Atlantic stingray *Hypanus sabinus*, in the skate *Raja erinacea* or in the ray *Urobatis halleri* for examples. Apart from the presence or absence of a ZD, it has been reported that the relative abundance of cysts at different stages of spermatogenesis varies seasonally according to species. As observed for *S. acanthias*, higher number of cysts containing mature spermatids or higher number of spermatozoa in seminal vesicle generally correlate with the mating period for sharks. In *S. canicula* (Carcharhiniformes, wide geographic range, Northeast Atlantic), mature spermatids containing cysts increase from April through to August and the greatest number of spermatozoa per seminal vesicle was observed from March through to May in species caught in the English Channel ([Garnier et al., 1999](#)). In Epaulette shark, *Hemiscyllium ocellatum* (Orectolobiformes, tropical, Western Pacific), higher amount of sperm storage occurs from August through to November, preceding mating period in December. In Starspotted smooth-hound *Mustelus manazo* and in Spotless smooth-hound *Mustelus griseus*, two Carcharhiniformes tropical species (Western Indian Ocean and Western Pacific), the highest number of cysts containing mature spermatids was observed in March and May, respectively, and accumulation of spermatozoa was greatest from December through to May. In both *Mustelus* species, it appears that spermatozoa production was at maximum before the June–August mating period. Among sharks, the Bonnethead *Sphyrna tiburo* (Carcharhiniformes, subtropical, Western Atlantic) appears as a special case since all stages of spermatogenesis are not present at all time of the year, a complete testicular regression and recrudescence is observed ([Parsons and Grier, 1992](#)). All the reports cited above concern sharks, what about rays? In the subtropical Myliobatiforms Atlantic stingray *Hypanus sabinus* (Western Atlantic) and round stingrays *Urobatis halleri* (Eastern Pacific), inactive phase of spermatogenesis was observed from March through to July and maximum production of mature cysts in winter (from August through to January in *H. sabinus*, December in *U. halleri*) preceding spring mating period when sperm stored in seminal vesicles will be used ([Tricas et al., 2000](#)). In lesser guitar fish *Rhinobatus annulatus* (Rhinopristiformes, subtropical, Southeast Atlantic), no spermatogenic

resting period was observed since all stages were found in the testes throughout the year. However, a peak in sperm production was observed from November through to January (Rossouw, 2014).

Control of Spermatogenesis

In Elasmobranchs, like in other vertebrates, the testicular function is hormonally controlled via a hypothalamus–pituitary–gonadal (HPG) axis involving the GnRH (Gonadotropin-releasing hormone) hypothalamic neuropeptide, pituitary gonadotropins LH (luteinizing hormone) and FSH (follicle stimulating hormone) and gonadal steroids. GnRH and gonadotropins acts by binding to their specific G-protein coupled-receptor (GnRHR, FSHR, LHR) expressed by their target cells. Three groups of GnRH (GnRH-I, GnRH-II, GnRH-III) have been identified in brain but it is classically considered that control of synthesis and release of gonadotropins is regulated by the GnRH-I localized in diencephalon. In Elasmobranchs, the transport of GnRH-I to pituitary occurs via the general circulation in absence of a direct vasculature such as the portal system found in mammals. Gonadotropins are heteromeric glycoproteins made of one common α subunit and of one specific β subunit (β -LH or β -FSH), the three subunits have been identified in *S. canicula* (Quérat *et al.*, 2001). However, presently, no FSH or LH receptors have been characterized in elasmobranchs, which underlines the work still to be undertaken in these species.

The Case of Leydig Cells

When testicular anatomy is presented, it is usual to present the seminiferous compartment in which spermatogenesis occurs and the interstitial compartment, which includes the Leydig cells. This pattern is probably true for amniotes but the presence of functional Leydig cells in elasmobranchs is still questioned. In amniotes, the Leydig cells are associated to androgen production and so what, they show an ultrastructure classically associated to steroid synthesis such as presence of mitochondria with tubular cristae, agranular endoplasmic reticulum and lipid droplets. In addition, they express key enzymes involved in the biosynthesis of steroids such as the 3β -hydroxysteroid dehydrogenase (3β -HSD) and 17β -hydroxysteroid dehydrogenase (17β -HSD). In elasmobranchs, Leydig cells have been described as absent or present according to authors and/or stages of development and/or seasonality. For example, they have been described as absent from the interstitial tissue of *Scyliorhinus stellaris* or rare in *Cetorhinus maximus* and *Scyliorhinus canicula* or present but undifferentiated in *Squalus acanthias*. Furthermore, Sertoli cells in these species show steroidal ultrastructure features and isolated cysts in *Squalus acanthias* or in *Scyliorhinus canicula* have the abilities to synthesize androgens. However, interesting studies conducted in the ray *T. marmorata* (Prisco *et al.*, 2008) has shed new light on the question. In fact, in this species, typical Leydig cells are observed in the interstitial compartment adjacent to cysts engaged in spermatogenesis but they have reduced cellular components when they are associated to cysts containing spermatogonia and, at the other end, when they are associated to cysts engaged in spermiation. Immunolocalization of 3β -HSD and 17β -HSD has confirmed a distinctive stage-related involvement of cells in steroid production: spermatogonia of the early stages, Sertoli cells of cysts containing spermatogonia, Leydig cells associated to meiotic stages and Sertoli cells in late spermatids stages.

Several studies, well reviewed by Awruch (2013), have analyzed steroid levels in relation with the seasonal reproductive cycle and spermatogenic stages. Briefly, androgens (mainly testosterone instead of 11-ketotestosterone) regulate development and maturation of cysts as well as the final stage of sperm maturation. Androgen receptor was primarily localized in premeiotic stages in the testis of *S. acanthias*, suggesting that androgens regulate the development of early stages of spermatogenesis (Cuevas and Callard, 1992). Among other steroids, 17α , 20β dihydroxyprogesterone (OHP) has been also identified and associated to cysts with late spermatids (Sourdaine and Garnier, 1993).

Conclusion

Elasmobranchs present a remarkable male genital tract that by some aspects, appears more related to the genital tract of amniotes than of anamniote species (epididymis for example). They have also characteristic features like the close association between the testis and the epigonal tissue or the diversity of testicular cells involved in steroidogenesis. What are the evolutionary meaning of these features? Endocrine and paracrine controls of spermatogenesis are still poorly understood while knowledge on the reproduction of elasmobranchs is still a challenge because of their vulnerability.

Glossary

A 'cellular association' Comprises groups of spermatids, various spermatocytes and spermatogonia, each at a specific phase of development, and constantly associated with one another.

'Duration of spermatogenesis' For a given species each step of spermatogenesis "has a constant duration; thus, germ cell differentiation unfolds as if regulated by a rigid time-scaled program" (Clermont, 1972).

Spermatogenesis Is a phenomenon in which germ cells in the testis multiply, form haploid cells that differentiate to produce millions of spermatozoa.

Spermatogonia Are the most immature germ cells of the seminiferous epithelium that divide to produce other germ cells, which subsequently proliferate and differentiate into spermatozoa.

Spermiation Is the process by which Sertoli cells move mature spermatozoa toward, and into, the tubular lumen, as free cells.

Spermiogenesis Is the last phase of spermatogenesis in which the haploid, round spermatid is differentiated into a spermatozoon.

'Stage of the cycle of the seminiferous epithelium' When a 'cellular association' is found in a 'cycle of the seminiferous epithelium' it is known as a 'stage', e.g., stages I to X in the Japanese quail (Lin and Jones, 1990).

The 'cycle of the seminiferous epithelium' Is defined as a "series of changes occurring in a given area of the seminiferous epithelium between two successive appearances of the same cellular association." (Leblond and Clermont, 1952).

The acrosome Is a cap-like, membranous, organelle covering the proximal part of the nucleus, and containing enzymes involved in the process of fertilization of the ovum.

The Centriolar complex Comprises the proximal and distal centrioles, with the latter forming the foundation upon which the midpiece of the spermatozoon is built. The distal centriole produces the central pair of the axonemal microtubules, and it determines the length of the midpiece. The axoneme/flagellum has the typical 9+2 pattern of microtubules.

The Chromatoid body Is an irregular structure of dense, reticular material found lying close to the Golgi complex and acrosome in round spermatids, but close to the centriolar complex in elongated spermatids.

The Granular body/helix Is a round to oval or irregular retiform and granular structure that is seen to lie close to the nucleus and the Golgi complex in younger spermatids. It forms an elongated helix in the older spermatids and in spermatozoa.

The 'Helical membrane' Is a helical external structure of the spermatozoon irrespective of its composition (Jamieson, 2007). It contains three different components: a protrusion/an extension of the core of the acrosome, mitochondrial helix, and microtubular helix in the spermatid.

The Manchette Is a temporary sleeve of microtubules, circular or longitudinal, surrounding the nucleus, and thought to assist in shaping of the nucleus during spermiogenesis.

The Perforatorium Is a fibrous structure consisting of parallel bundles of filaments; it is embedded in the endonuclear canal and projects into the deep and ample subacrosomal space of the acrosome, in most non-passerine birds.

'Wave of the seminiferous epithelium' Clermont (1958) defined the wave of the seminiferous epithelium "as a complete series of the successive cell associations found along a seminiferous tubule."

Introduction

Spermatogenesis is similar in all vertebrates, with variations, which are species-specific. Spermatogenesis is rapid in birds, and therefore, spermatozoa are produced in large numbers over a short period of time. There are over 10,000 species of birds divided into passerine and non-passerine groups. Spermatogenesis has been poorly studied in birds although they constitute more than half of all vertebrates (see Aire (2007a, 2014)). However, spermatogenesis is the process by which diploid cells are transformed into haploid cells, which then differentiate during the next phase, spermiogenesis, into spermatozoa. During spermiogenesis, the spherical nucleus of the spermatid elongates and its chromatin undergoes transformations. Major events are the elaboration of the precursors, and subsequent development, of the acrosome, as well as nuclear morphological transformation into an elongated organelle with condensed chromatin. The centriolar complex is structurally similar to that of vertebrates generally, but differences exist not only between birds and other vertebrates, but also between groups of birds. Only concise, basic features of the various complex processes will be provided, here. For more advanced and detailed knowledge of spermatogenesis it is necessary to refer to selected references and reviews, some of which are provided, appropriately. For proper perspective, it is also necessary, first, to introduce very concisely the structure and nature of the avian male reproductive organs (Aire, 2007b). Jamieson (2007) has an excellent account of sperm structure in birds.

Avian Testis and Its Excurrent Ducts

Birds retain their testes within the abdomen, unlike in most mammals, but genetically controlled biochemical processes permit the testis to function efficiently in spite of the high core body temperature (Mezquita *et al.*, 1998). Avian testes are, however, generally similar to mammalian testes, in structure, composition, and color. Although there exists some variability in size between the bean- or oval-shaped left and right testis, yet each unit weight of the organ probably functions equally (see Aire (2007b)).

The main components of the testis, the seminiferous tubules, surrounded by the interstitium, are generally similar to those of mammals in composition and structure (Aire, 2007b). The columnar epithelium of the seminiferous tubule, usually branched in birds, contains fixed, somatic, non-germinal, Sertoli cells, which surround, support and nourish the series of germ cells. As in mammals, the germ cells move toward the tubular lumen, in a successive series of spermatogonia, primary and secondary spermatocytes, and spermatids; the latter differentiate into spermatozoa. Both the spermatid and spermatozoon are haploid. Spermatozoa leave the seminiferous epithelium and swim in the rather copious avian luminal testicular fluid (see Aire (2007b)) into, and through, the excurrent duct system.

The avian excurrent duct system comprises various ducts (the rete testis, efferent, connecting and epididymal ducts) within a small but complex epididymis, and a wavy ductus deferens (Aire, 2007b). These are, as in mammals, regulated by complex structural, endocrine, and paracrine, interactions (Skinner *et al.*, 1991; Hermo *et al.*, 2010).

Spermatogenesis in Birds

Within the seminiferous epithelium spermatogonia proliferate, the products of this undergo meiosis, and ultimately differentiate from round, non-motile cells into highly elongated, motile, male, gametes, the spermatozoa. This process, spermatogenesis, is 'midwived' by the Sertoli cells, as in mammals. The various cell types (spermatogonia, leptotene, zygotene, pachytene, diplotene primary spermatocytes and secondary spermatocytes, and spermatids) and the morphophysiological events taking place in the germ cells are, also, generally similar to those of mammals in which they have been best studied and elucidated (Clermont, 1972; Hermo *et al.*, 2010).

Spermatogonial Renewal and Proliferation

Spermatogenesis is a continuous, sustained process that must depend on regular renewal and availability of spermatogonia, which are the most primitive, progenitor, germ cells, from which other germ cell series originate. Spermatogonial renewal has been studied in numerous mammals (see Hermo *et al.* (2010)) but only two reports are available for birds. Clermont (1958) has demonstrated two types of spermatogonia, type A (stem cell; resting) and type B, with the latter differentiating into type C spermatogonia in the Mallard. In the Japanese quail (Lin and Jones, 1992), there is the dark type A (Ad) spermatogonium that replicates itself (stem cell renewal); one of them enters the proliferation phase of spermatogenesis by dividing into two variant spermatogonia, a pale type A (with Ap₁ and Ap₂ sub-variants) and type B (Fig. 1). There are fewer spermatogonial (mitotic) divisions in birds than in mammals. The type B spermatogonium proliferates through a definite series of primary and secondary spermatocytes. The secondary spermatocytes undergo meiosis, each producing two spermatids, which differentiate into spermatozoa (Fig. 2). Thus, the germ cells grow

Fig. 1 A serial representation of stem cell renewal and spermatogonial proliferation in the Japanese quail. Ad=Dark type A spermatogonium; Ap1=pale type A1 spermatogonium; Ap2=pale type A2 spermatogonium; B=type B spermatogonium; 1^{IV}=primary spermatocytes; 2^{IV}=secondary spermatocytes. The Arabic numerals indicate the number of cells in each germ cell series. Fig. 2 provides the time of occurrence of each cell type and stage during the cycle of seminiferous epithelium. From Lin, M., Jones, R.C., Blackshaw, A.W., 1990. The cycle of the seminiferous epithelium in the Japanese quail (*Coturnix coturnix japonica*) and estimation of its duration. *Journal of Reproduction and Fertility* 88, 481–490. Reproduced by permission of the Society for Reproduction and Fertility (1990).

older as they undergo transformation and move from the basement membrane of the seminiferous epithelium toward the tubular lumen. Spermatogenesis is a carefully, synchronized, orderly, precise, and unique biological event that, although generally similar in vertebrates, has unique elements for each species of animal. The evolution of spermatozoa from spherical undifferentiated cells is one of the most intriguing biological events, and knowledge of the numerous, complex, and intricate processes involved is necessary for better understanding of this phenomenon.

The Cycle of the Seminiferous Epithelium

The epithelium of a transverse section of a seminiferous tubule comprises germ cells and Sertoli cells, with the germ cells arranged in a concentric manner from the basement membrane, where the most primitive spermatogonia are situated, to the luminal border, where the most advanced germ cell types, that is the spermatids and spermatozoa, are situated. Thus, groups of spermatids at a given step of development are *constantly* associated with *certain specific* groups of spermatocytes and spermatogonia, each *at a specific phase of development* (Perey *et al.*, 1961), as well as with the same groups of nurse cells, the Sertoli cells (Skinner *et al.*, 1991). This is a specific, unique and constant ‘cellular association’ of successive generations of cells arising from the same spermatogonium, with each generation of cells being linked physiologically in a syncytium that ensures a synchronized process of development. It is therefore expected that there are several specific cellular associations, each occupying a small portion of the epithelium along the length of the seminiferous tubule (Fig. 2). For example, in a small space of the seminiferous epithelium, from the lumen to the basement membrane of the seminiferous epithelium in column III (‘cellular association’ or ‘stage’ III) (Fig. 2), there are always two spermatids at steps 3 and 11, which are always, specifically, and invariably associated with pachytene primary spermatocytes, type B spermatogonium, pale type Ap2 spermatogonium, and type Ad spermatogonium, while column X (Fig. 2) has step 10 spermatids, always associated with secondary spermatocytes, pachytene primary spermatocytes, type B spermatogonium, pale type Ap1 spermatogonium, and type Ad spermatogonium.

The seminiferous epithelium has 6 (numbered I to VI) cellular associations in the rooster (Courot *et al.*, 1970) and 10 (I to X) in the Japanese quail (Lin and Jones, 1990; Aire, 2007a). There are 14 in the rat (Leblond and Clermont, 1952). However, whereas only one cellular association occupies the epithelium of a transverse section of the seminiferous tubule in most mammals, there are *multiple, heterogeneous, or mosaic patterns* of cellular associations in a similar section in birds and primates (see Aire (2007a)). These species-specific numbers of cellular associations are arranged in an orderly, predictable succession, for example, I to X in the Japanese quail (Fig. 2) (Lin and Jones, 1990), to constitute a ‘cycle of the seminiferous epithelium’ within an area or a segment of the seminiferous tubule. Each cellular association within the cycle is known as a ‘stage of the cycle’.

The ‘wave of the seminiferous epithelium’ is regarded as the completion of a full series of cellular associations (e.g., I to X, for the Japanese quail) between two successive appearances of the same stage (e.g., I to X, followed by another cycle beginning with I) along the length of the seminiferous tubule (Perey *et al.*, 1961). Only a few reports on this phenomenon are available in birds (Lin and Jones, 1990), and in the human primate, apparently because they have heterogeneous cellular associations, unlike in most mammals (see Aire (2007a)).

A stage number, e.g., stage III of I to XIV stages of the cycle of the seminiferous epithelium in the rat, may be missing. This phenomenon, known as ‘modulation’ (Perey *et al.*, 1961), has not yet been reported in birds, apparently due to branching of the seminiferous tubules (Lin and Jones, 1990). The duration of spermatogenesis, i.e. from type Ad spermatogonial division to the release of spermatozoa from the seminiferous epithelium, is constant and independent of season (de Reviers, 1975). It is quite short in birds, being between 12 and 13 days (de Reviers, 1975; Marchand *et al.*, 1977; Lin and Jones, 1990, 1992; Aire, 2007a, 2014), unlike 25–65 days in several species of mammals (Clermont, 1972). In addition, although the number of spermatids produced per stem cell is much greater in mammals (128-fold), birds, however, invest heavily on sperm production. For example, the duration of spermatogenesis is short, and the gonosomatic index (% of testis weight relative to body weight) is much higher in birds than in

mammals (Clulow and Jones, 1982; Møller, 1991); it has been established that testis size and sperm production are highly and positively correlated.

Spermiogenesis in birds

Introduction

Spermiogenesis is the last phase of spermatogenesis in which the haploid, round spermatid is differentiated into a spermatozoon. The spermatids arising from the same secondary spermatocyte form a syncytium, and each of them has a spherical nucleus, containing finely granular and a few clumps of chromatin (Figs. 3 and 4). A large Golgi complex, surrounded by numerous mitochondria, lies close to the nucleus. Numerous long strands of rough endoplasmic reticulum, a few other mitochondria and lysosomes are scattered throughout the cell. The centriolar complex, comprising the proximal and distal centrioles, lies free in the cytoplasm, with the distal centriole making contact with the cell wall, from which junction the flagellum extends freely into the intercellular space. During spermiogenesis, certain organelles of the round spermatid are remodeled, completely or partially, some are newly differentiated organelles, and some are discarded. The round spermatid loses about 97% of its volume, with the nucleus losing about 96% of its own volume (see Aire (2007a)).

As for spermatogenesis, the nomenclature and terms used in mammalian spermiogenesis are generally adopted for birds. However, only a few reports on this phenomenon are available for birds, in general. A concise description of the main features of spermiogenesis, first, in the non-passerine, and then in the passerine, bird will be provided, below. The step-wise method will be employed in order to place emphasis on relative or spatiotemporal developmental changes in the spermatid. The major determinants of steps of spermiogenesis are acrosomal, nuclear, centriolar and mitochondrial developmental changes. In general, twelve steps of spermiogenesis have been described in a few birds, such as the turkey and Japanese quail (see Aire (2014)). Each step of spermiogenesis comprises specific, landmark, structural modifications in spermatid organelles.

Non-Passerine Spermiogenesis

Steps of spermiogenesis

In Step 1, the Golgi complex displays numerous small, round, granules, the proacrosomal granules (Fig. 3).

Step 2: Most of the proacrosomal granules fuse together to form a large acrosomal vesicle.

Step 3: Both the acrosomal vesicle and centriolar complex gradually approach the nucleus, and subsequently, the acrosomal vesicle attaches to the putative proximal pole of the nucleus.

Step 4: As the acrosomal vesicle develops a broad base on the nucleus and begins to elongate, it becomes the acrosome. The nucleus and elongating acrosome then move toward the cell membrane, with which the acrosome makes contact. Thus, the spermatid lies closer to the Sertoli cell for nourishment, support and possible modeling. The centriolar complex attaches to the nucleus, close to the acrosome. A few, scattered microtubules appear around the nucleus.

Step 5: The nucleus contains finely granular chromatin, and begins to elongate, while the cytoplasm gradually migrates posteriorly, away from the nucleus. The centriolar complex also commences migration toward the caudal pole of the nucleus, to which it attaches at a shallow implantation fossa. The caudal part of the distal centriole attaches to the cell membrane at a ring-like thickening, the annulus. An evagination from the acrosomal base into the nucleus forms the precursor of the perforatorium rod that projects into a corresponding invagination of the nuclear membrane, the fledgling endonuclear canal.

Step 6: The elongated and wavy nucleus contains moderately electron-dense, granulo-filamentous chromatin. The fibrous perforatorium rod inserts in the endonuclear canal, and both grow further. The perinuclear microtubules form a sleeve of circularly oriented microtubules, the circular manchette (CM), extending from the acrosome-nuclear junction to the centriolar complex, caudally. Close to this complex lies a granular, round body known as the chromatoid body whose function is unknown. Mitochondrial migration into the trailing cytoplasm continues.

Step 7: The acrosome elongates further, and nearly occupies the entire proximal surface of the elongated and narrow, vermiform, nucleus. Also, an excavation of the base of the acrosome, the subacrosomal space, develops and overlies the blunt proximal end of the nucleus. The mitochondria in the caudally trailing cytoplasm elongate significantly.

Step 8: The proximal end of the nucleus narrows into a pointed rostrum, which projects into the deepening and enlarging subacrosomal space. The nuclear chromatin forms dense, rod-shaped granules. Following considerable narrowing of the nucleus, the CM may transform rapidly into the longitudinal manchette (LM); elements of both sets of manchette may occur concurrently, during this re-arrangement process.

Step 9: The LM is fully established, extending farther caudally into the trailing cytoplasm than the CM does. The function of the manchette is not clearly understood, but it is thought that it is responsible for shaping the nucleus. However, the acrosome appears as an elongated cone, and the perforatorium rod extends more deeply into the rostral part of the subacrosomal space. The perforatorium, *inter alia*, is thought to assist in elongating and supporting the acrosome, during its development (Baccetti *et al.*, 1980), but not all non-passerine birds possess this structure.

Step 10: The nucleus elongates further, and contains electron-dense, compactly packed, spherical chromatin. Mitochondrial elongation continues.

Fig. 3 A diagrammatic representation of the major changes that occur during spermiogenesis in non-passerine birds. The numerals represent the steps of spermiogenesis. Nu=nucleus, G=the Golgi complex, C=the centriolar complex, Mt=mitochondrion, F=flagellum, P=acrosomal granule, Dc=distal centriole, Ac=acrosome, dark arrowhead=microtubules of the circular manchette, white arrowhead=developing perforatorium and endo-nuclear canal, white broad arrows=longitudinal manchette, double dark arrows=disintegrating longitudinal manchette, Pp=principal piece of the flagellum, dark notched arrow=perforatorium rod, Ms=mitochondrial sheath. Not drawn to scale.

Step 11: The nuclear chromatin forms larger, compact, electron-dense granules. A major change in this step is the patchy break-up of the LM.

Step 12: During the last step of spermiogenesis the LM disappears completely, thus, allowing the elongated mitochondria to move toward the midpiece and form concentric rings around the distal centriole. The mitochondrial sheath, so formed, supplies energy for this motile cell. The spermatid becomes a mature spermatozoon, and ready for spermiation, which involves the movement of the mature spermatid toward the lumen of the seminiferous tubule, as the sleeves of cytoplasm of the Sertoli cell release

their hold on it. The redundant cytoplasm, containing unused organelles that include the Golgi complex and endoplasmic reticulum, becomes the *residual body*, which is phagocytized by Sertoli cells.

Passerine Spermiogenesis

There are several similarities as well as differences in the process of spermiogenesis between non-passerine and passerine birds. The organelle content and disposition of the round spermatid is similar between them, in most particulars, but a granular body, not

homologous to the chromatoid body of non-passerine birds, lies close to the Golgi and centriolar complexes in passerine birds. Both the proximal and distal centrioles are present in the spermatid, but the loss of the proximal centriole has been reported during spermiogenesis, in some passerine birds (Aire, 2014). The structure of the spermatozoon of the passerine bird has been reviewed recently (Aire *et al.*, 2017).

Steps of spermiogenesis

Step 1: The nucleus is round and contains fine granulofilamentous chromatin. A large Golgi complex, the centriolar complex, granular body, and mitochondria lie close together in the same region of the cytoplasm (Fig. 4). Numerous, small vesicles, proacrosomal vesicles, rather than granules, each with an encircled, smaller dense granular content proliferate from the trans-Golgi network zone. These are different from the homogeneous proacrosomal granules of non-passerine birds.

Step 2: Most of the proacrosomal vesicles coalesce to form a single, large, bipartite, acrosomal vesicle, comprising the wall or acrosomal crest, and its much smaller, dense granular content, the acrosomal core (Jamieson, 2007; Aire, 2014).

Step 3: The acrosomal vesicle, still linked with the Golgi complex, attaches to the nucleus, and the centriolar complex extends from its contact with the cell wall to the nucleus, attaching to it, close to the acrosomal vesicle. The annulus is very poorly developed or absent in passerine birds. The granular body lies close to or makes contact with the free end of the proximal centriole.

Step 4: The acrosome becomes conical in shape, with a broad dense acrosomo-nuclear junction. The centriolar complex, along with the granular body and Golgi complex, migrates from close to the rostral pole, toward the caudal pole, of the nucleus. The proximal and distal centrioles articulate at about 45° with each other, with the granular body attaching to the free end of the proximal centriole.

Step 5: The acrosome elongates and indents the euchromatic nucleus deeply. Concurrently, the cytoplasm, as in non-passerine birds, commences migration caudally, away from the nucleus.

Step 6: The acrosome displays signs of twisting in a spiral fashion. The nucleus, now shorter and goblet-shaped, contains electron-dense granular chromatin.

Step 7: The narrower nucleus elongates further. The mitochondria elongate considerably and align themselves, in four rows, alongside the axoneme. A set of obliquely aligned microtubules lie very close to the inner part of the cell wall; these microtubules are not homologous or analogous to the manchette of non-passerine birds. The axoneme, with the typical 9+2 microtubular configuration, develops fully. Unlike in non-passerine birds, there is no clear demarcation between the midpiece and principal piece, both of which have the dense outer fibers.

Step 8: The nucleus shortens, again, becoming dumb-bell shaped, and the chromatin forms variably arranged, dense, thick, rod-like strands. The granular body elongates alongside the distal centriole. Remarkably, the microtubules commence transformation into loose bundles that migrate toward the axoneme, in a helical fashion. The bundles extend from the acrosomo-nuclear junction into the caudally trailing cytoplasm. The acrosome is longer than the nucleus, and there is evidence of commencement of helical shaping.

Step 9: The helical formation of the acrosome increases, and the acrosomal core is, now, separated from the acrosomal crest, only rostrally. The acrosome also indents deeply a narrower and elongated nucleus containing thick strands of linearly arranged chromatin. The microtubular bundles form a compact microtubular helix around the nucleus, granular body, and the axoneme. The elongated strands of mitochondria join end-to-end, and fuse to form longer strands around the axoneme.

Step 10: The acrosome shows more pronounced alternating convexities and concavities as its spiraling process accentuates. The wall of the convexities is drawn out as a ridge, forming the 'helical membrane' or 'keel'. The acrosome is longer than the nucleus whose helical shape is also well established, as the chromatin forms denser, spherical, compactly packed granules.

Step 11: The acrosomal core completely fills the crest portion, including the keel, now sharply pointed. The chromatin of the helical nucleus is densely homogenous, unlike in most non-passerine birds. A single mitochondrial helix runs closely along with the microtubular helix. All other organelles, and possibly the proximal centriole, are in place and structurally definitive.

Step 12: This is the last step, and the organelles are refined and displayed as found in the spermatozoon; the spermatozoon is spirally shaped, the acrosome is longer than the nucleus, and the flagellum is extremely long, unlike in non-passerine birds. Spermatozoa undergo spermiation, as in non-passerine birds, but during this process some of them lose their microtubular helices, while others lose theirs thereafter, in the excurrent ducts of the testis.

General Remarks on Avian Spermatogenesis

Spermatogenesis is similar in vertebrates generally, with specific or unique differences between orders, families and even species. There are therefore differences in this phenomenon between the two main avian groups, passerine and non-passerine birds. Avian spermatogonial divisions are fewer, and therefore, fewer spermatozoa are produced per spermatogonium than in mammals, but spermatogenesis is much more rapid in birds. Acrosomogenesis produces a relatively short, conical, acrosomal complex comprising the acrosome and perforatorium in non-passerine birds, but a highly elongated, helical, bipartite, acrosome devoid of a perforatorium, and as long as, or longer than, the nucleus in passerine birds. The nucleus loses much of its volume, becomes highly elongated and narrow, and its chromatin ultimately condenses considerably in all birds. The distal centriole in non-passerine birds differentiates into a short rod in the mid-piece but it becomes extremely elongated in passerine birds, and not clearly demarcated from the considerably elongated principal piece of the flagellum. The proximal centriole is found in non-passerine birds generally, but

reported in spermatids and spermatozoa of only a few passerine birds. Passerine, but not non-passerine, spermatids develop five helically shaped organelles: acrosomal, nuclear, mitochondrial, granular, and microtubular helices, with the latter two structures being absent altogether in non-passerine birds.

The Insect Spermatozoon

Introduction

Insects are the largest and most diverse group of animals. Their richness is the result of several factors such as their relatively old origin (Pragian, 411–407 million years ago) (Whalley and Jarzembowski, 1981; Engel and Grimaldi, 2004), their morphological innovations making them highly adaptable to a variety of diets, the acquisition of wings, their capacity to tolerate variations of environments (Mayhew, 2007) and, more important, their impressive reproductive fitness allowing them to colonize suitable environments. Insects are characterized by a relatively short lifespan which facilitates the accumulation of mutations and a faster genetic divergence; this could explain their particular high speciation rate.

Insects display a great variability in sperm structure in comparison to other groups of animals. It was suggested that the great sperm diversification is the result of an intense sexual selection acting directly on the sperm form, even though we currently have only a rudimentary understanding of the adaptive significance of such variations (Sivinski, 1980; Pitnick *et al.*, 2009). A sperm competition between the ejaculates of different males at fertilization (polyandry) can also contribute to the sperm modifications (Parker, 1970, 1998), as well as after the sperm entry into the female genital tract, due to a sperm-female interaction (post-copulatory selection when polyandry is occurring), through which mechanisms enabling females to bias the outcome of sperm competition in favour of the sperm of certain males (cryptic female choice) (Eberhard, 1985, 1996) may be activated.

Insect Spermatogenesis

Insect testes contain several germ cyst cells each consisting of a certain number of diploid spermatogonia. After a variable number of mitosis, the cysts of primary spermatocytes are produced which move down along the testes and enter meiosis. At the end of the two meiotic divisions, haploid spermatids are formed, the number of which depends on the number of initial spermatocytes. After the first meiotic division the number of the secondary spermatocytes becomes double and the same occurs after the second meiotic division to produce spermatids. Thus, if there were 16 spermatocytes, at the end of the meiotic process we will obtain 64 spermatids. The number of spermatids, however, is reduced in those insects characterized by haplodiploidy and in those where parthenogenesis is a frequent mode of reproduction, with the males' haploid and meiotic process abolished. The same occurs in paternal genome elimination (PGE) (Dallai *et al.*, 1999, 2000; Normark, 2009). The number of spermatids may also depend on the size of germ cells with evident reduction when giant sperm are produced (Pitnick *et al.*, 2009). Contrary to the rule in other organisms, during insect spermatogenesis, the second meiotic division does not show centrosome (centriole+dense material surrounding it) duplication (González *et al.*, 1998; Callaini *et al.*, 1999) and the spindle exhibits only one centriole at each pole. Thus, at the end of meiosis, spermatids will receive only one centriole (Fig. 1(A) and (E)). The development of spermatids is syncytial, due to the presence of large intercellular bridges (ring canals) which allow the maintenance of synchronism among germ cells of a cyst. Spermatids only become individualized at the end of spermiogenesis. During the post-meiotic phase, transcriptional activity, at least in *Drosophila* males, is limited (Olivieri and Olivieri, 1965); thus, structural modifications occurring in spermiogenesis, depends on genes transcribed in primary spermatocytes.

Insect Spermiogenesis

The typical insect sperm is an elongated cell provided with an acrosome at the apical nuclear region, a long nucleus and a posterior long flagellum. The basal body, the centriole adjunct, the axoneme, the mitochondrial derivatives and the accessory bodies are present beneath the nucleus. All these sperm components are the results of the process of spermiogenesis which transforms the globular spermatids (Fig. 1(A)) into elongated sperm cells. The acrosome originates from the activity of the Golgi apparatus (Fig. 1(A)). It can be very elaborated and usually shows an inner "perforatorium" (Fig. 1(B)) of filamentous material containing actin, or it can be reduced to a simple apical vesicle (Fig. 1(C)) or completely missing. The nucleus, globular shaped at the beginning of spermiogenesis (Fig. 1(A)), becomes elongated, cylindrical shaped and with compact dense chromatin (Fig. 1(C)). During spermatid maturation, nuclear histones are replaced by basic structural proteins or protamines (Hecht, 1995) which neutralize the acidic charge of DNA, determining the chromatin compaction. The basal body derives from the centriole (Fig. 1(E)) after some modifications (Fig. 1(F)). It is involved in the production of the flagellar axoneme, which consists of a microtubular complex. As mentioned above, insect spermatids have only one centriole, but two or more centrioles can be found in some insects, due to a non-conventional spermatogenesis (Isoptera, Phthiraptera, Thysanoptera). The centriolar region usually exhibits a granular dense material surrounding the basal body, known as centriole adjunct (Fig. 1(F)), often extending along the flagellum in the shape of two dense structures, the accessory bodies, which are parallel to the axoneme. In the dipteran Diopsidae a prominent central dense band is present all along the flagellum. In the early spermatids, the centriole+dense material called pericentriolar material (PGM), constitute the centrosome. At the beginning of spermiogenesis, the centriole becomes the basal body and the proteins

Fig. 1 (A) Spermatid of the phasmatodean *Timema poppensis* showing the “nebenkern” (nk), the nucleus (N), the basal body (arrow) producing the flagellum (F). (F) The basal body, surrounded by the centriole adjunct material of the same species in the aged spermatid. (G) Cross section of the sperm flagellum of the heteropterian *Pyrrhocris apterus* with the axoneme 9+9+2 and the

of the PGM, γ -tubulin in particular, are involved in the production of numerous microtubules around the spermatid components for their elongation and shaping. During the spermiogenesis additional material is deposited beneath the nucleus to form the centriole adjunct (Dallai *et al.*, 2016a). The mitochondrial derivatives are the final result of the series of transformations, including aggregation and fusion, of spermatid mitochondria. After these processes, a “nebenkern” is formed (Fig. 1(A)) and, in turn, from this, two structures are produced which accompany the axoneme for most of its length (Fig. 1(G)). Transcripts encoding the proteins needed for mitochondrial morphogenesis are made in primary spermatocytes, but translation is delayed until the meiosis ends. Mitochondrial derivatives can be reduced to a single one or be greatly enlarged, as for instance in the zorapteran *Zorotypus impositus*, the neuropteran *Perlamantispa perla* (Fig. 1(P)), the coleopteran *Divaes bipustulatus*, and the dipterans *Diaemopsis* ssp (Kotrba *et al.* 2016). Mitochondrial derivatives have a dense matrix with a paracrystalline material (Fig. 1(G),(H) and (L)) containing the protein crystallomitin, characterized by a high content of proline and insoluble polypeptides with S-S disulphide cross-link. Differently from other animals, at fertilization, the whole sperm enters the egg, mitochondrial derivatives included, and these structures, with their paternal mt-DNA, are found almost intact after hatching and can be recovered in the faeces of the larva (Pitnick and Karr, 1998). The flagellar axoneme in the basal springtail Collembola, consists of a simple 9+2 (that is two central singlet microtubules, surrounded by a crown of 9 doublet microtubules) as an ancestral condition. This simple model is also present in some advanced orders, such as Mecoptera and Siphonaptera, as a derived condition acquired by reversal. Starting from the entognathan Diplura, through the ectognathan Archaeognatha and Zygentoma and up to all pterygote insects, the flagellar axoneme becomes more complex due to the presence of a set of outer accessory microtubules giving rise to a 9+9+2 axonemal model. The acquisition of this outer crown of tubules is an important synapomorphy of Insecta (=Ectognatha)+Diplura. The accessory tubules are formed during late spermiogenesis from the proliferation of the B-tubule of each microtubule doublet (Fig. 1(I) and (J)). The accessory tubules are more stable than the doublets due to the presence of associated proteins (MAPs) in their tubular walls. During the production of these tubules, a dense material is also deposited between two adjacent accessory tubules. As mentioned above, the elongation and shaping of the spermatid components is mediated by a series of cytoplasmic microtubules, which surround the different structures for all the spermiogenesis (Fig. 1(K)), but disappearing at the end of the process.

Insect Sperm Structure

The sperm is a specialized cell for reproduction. In insects, they usually are elongated cells, with an anterior head and a posterior tail (Fig. 1(L)). In *Drosophila bifurca* the sperm reaches up to 6 cm in length, 20 times the size of body specimen; in the deferent ducts the sperm rolled up to form filamentous balls (Fig. 1(M)). In the hymenopteran *Cotesia congregata*, the shortest sperm, only 7 μ m long, has been described so far. The sperm has a plasma membrane with a more or less complex glycocalyx. In some Orthoptera, it forms a dense thick layer with a complex inner organization, surrounding the sperm cell (Fig. 1(N)); in moths the glycocalyx is quite elaborated and consists of long laciniate appendages (Fig. 1(P)).

The sperm has an anterior acrosome the inner part of which, the perforatorium, can extend into the anterior axial nuclear region. The acrosome is rich in enzymes which can help the sperm entry the egg at fertilization. Moreover, in *Drosophila* ssp, the plasma membrane at the acrosomal level contains some glycosidases which serve for the sperm-egg interaction at fertilization. The α and β -acetylglucosaminidases are present on the sperm membrane of fertile males and the corresponding site of β -acetylglucosamine has been detected on the micropyle of the fruitfly egg (Perotti and Pasini, 1995). Glycosylation is retained of great importance for sperm-egg interaction.

The nucleus is elongated and contains compact chromatin material (Fig. 1(D)), unable to activate transcription. In some insects, such as Lepidoptera and the neuropteran *Perlamantispa perla*, characterized by heteromorphism, two types of sperm are present, the aberrant of which, is not involved in fertilization (Figs. 1(O) and 3(M); Jamieson *et al.*, 1999; Birkhead *et al.*, 2009).

Posterior to the nucleus, a centriolar region is adapted to host the basal body and the beginning of the flagellar components. The dense material of the centriole adjunct surrounds the basal body and the two mitochondrial derivatives. In a few examples, the material of the centriole adjunct is missing, but usually it extends along the flagellum on both sides of the axoneme adhering to

mitochondrial derivatives showing three crystallized areas (asterisks). the mitochondrial derivatives to constitute the accessory bodies (Fig. 1(L)). A direct connection of these structures to the centriole adjunct has been well ascertained (Dallai *et al.*, 2016a). The function of the centriole adjunct is not clear; it has been suggested that it provides reinforcement to the head-tail connection of the sperm or, together with the mitochondrial derivatives and the accessory bodies, it contributes to a better integration of the sperm components, making the sperm movement more uniform.

The flagellar axoneme of insects is the structure for the sperm motility. However, in several orders, there is the tendency towards a progressive degeneration up to the disappearance of the axoneme, with the consequent sperm immotility. This is evident in the basal apterygotan Protura, in the mayfly Ephemeroptera, in termites, among Hemiptera Sternorrhyncha, and within single families of Trichoptera (Hydroptilidae), of higher Coleoptera (Ptiliidae) and Diptera (Psychodidae and Cecidomyiidae). It has been suggested that the evolution of aflagellated and immotile sperm may be due to the removal of selective pressure generated by sperm competition (Morrow, 2004). The sperm movement is due to the interaction of the two arms present on the A-tubule of each microtubular doublet, with the B-tubules of the adjacent doublet. As known, such arms contain an adenosine triphosphatase (ATPase) that is responsible for the bending waves of live sperm tail (Satir, 1968; Summers and Gibbons, 1971). The binding and hydrolysis of ATP would cause a cyclic change in the angle of the arms which coordinated with the repeated making and braking of their attachment to successive binding site along the length of the B-tubule, would result in the sliding of one tubule along the other. Since the axonemal tubules are anchored within the cell body, the sliding is translated into bending of the flagellum. The loss of one dynein arm, as it occurs in some insect sperm, such as mayfly (Ephemeroptera) or caddisfly (Trichoptera) does not prevent the microtubule sliding and sperm movement which, instead, is lost when both arms are missing. In these cases, the subsequent developmental step is the loss of the whole flagellar axoneme with the sperm becoming immotile. A clear example of this process can be seen among the groups of the Hemiptera Sternorrhyncha (from Aphidoidea to Coccoidea). There are usually two mitochondrial derivatives of the same size and they accompany the axoneme for almost the whole its length (Fig. 1(L)); they end before the tail end. Sometimes they can be of different size or become giant structures as it occurs in the zorapteran *Zorotypus impolitus* (Fig. 2(M)), or in the not functional sperm of the neuropteran *Perlamantispa perla* (Fig. 1(O)), or to be missing altogether, as in the higher Phasmatodea. As mentioned above, the mitochondrial derivatives do not seem to be involved in some functional activities; they seem to play a passive role in sperm motility and after fertilization they maintain their structure apparently without modifications and are discharged almost intact with larval faeces. Their contribution could be to modulate the undulation of the axoneme. A similar function can also be suggested for the accessory bodies. In short sperm the accessory bodies are small in size or are lacking. According to Werner and Simmons (2008), sperm movement exhibits different levels of complexity: when the flagellum has a simple 9+2 axoneme, it shows a simple planar flagellar wave of low frequency; when sperm flagellum has a 9+9+2 axoneme, however, a double helical movement pattern is realized. This movement, which is the common pattern shared by insect sperm, consists of a small amplitude, high frequency wave which is superimposed on a high amplitude, low frequency wave (Werner and Simmons, 2008). In some insects a bidirectional movement has also been described, the sperm being able to perform forwards as well as backwards movement. Activation of sperm motility involves structural and metabolic changes to the sperm, or chemical stimuli leading to the initiation of motility. Such stimuli can be external agents which modify the flagellar membrane allowing seminal fluid components to entry the sperm cell (Osanai *et al.*, 1991), other than the pH, osmotic factors and the presence of oxygen (Werner and Simmons, 2008).

A synthetic overview on the sperm types exhibited by insects is extremely difficult as a great variation on the size and shape of their sperm components is quite common (Dallai, 2014; Dallai *et al.*, 2016b). In the basal hexapod Collembola (Springtails), a simple sperm with a flagellar axoneme of 9+2 type is present. The main characteristic of their sperm is realized at the end of spermiogenesis, when a flattened or globular sperm cell is produced, as the result of the nucleus and flagellum wrapping around an extracellular cavity filled with secretion. Moreover, a long extracellular cylindrical structure adheres to the acrosomal apex (Fig. 2(A) and (B)). An indirect sperm transfer by spermatophores, deposited by males on soil substrate and picked up by the female with its genital opening to transfer it into the spermatheca, is the normal mode of reproduction in this group. Protura

(Coneheads) have an aberrant motile sperm with a flagellar axoneme devoid of central tubules and with several peripheral microtubule doublets showing only inner dynein arms (Fig. 2(C) and (D)). Aflagellated immotile sperm are also present in some families. Diplura (Two-pronged bristletails), like all Ectognatha, have acquired 9 accessory outer microtubules external to the 9+2; these tubules, however, shift from their regular position close to the doublets to one side of the axoneme at the end of spermiogenesis (Fig. 2(E) and (F)). The accessory microtubules have also been acquired by Archaeognatha (Bristletails) (=Microcoryphia) and Zigentoma (Silverfish). The former group has a flagellum folded back at half its length, giving the wrong impression of a sperm with two axonemes in the same cytoplasm. Moreover the accessory microtubules, as in Diplura, are placed on two opposite sides of the 9+2 complex (Fig. 2(G)). Zygentoman sperm, to the contrary, is of a conventional type (Fig. 2(H)). The sperm are usually conjugated pairwise and in *Tricholepidion gertschi* fuse mature sperm form binucleate, biflagellate units. The Paleoptera, Odonata (Dragonflies and Damselflies) and Ephemeroptera (Mayflies), exhibit quite a different sperm structure, even though from phylogenetic perspective the two groups are closely related. Ephemeroptera sperm axonemes have lost central tubules and the microtubule doublets have only inner arms (Fig. 2(I)). Aflagellated immotile sperm have been described in the group. Odonata, to the contrary, have a typical insect sperm with a 9+9+2 axoneme flanked by two mitochondrial derivatives and two accessory bodies (Fig. 2(J)). The sperm structure is highly variable among Neoptera. Polyneoptera, the group comprising about one third of the pterygote orders, evolved sperm characters independently in each major lineage, possibly as a consequence of the extreme diversity in their ecophysiological features. Among this group, the large order Orthoptera (Grasshoppers, Locust, Katydid) (Fig. 2(K)), Plecoptera (Stoneflies), Embioptera (Webspinners), Dermaptera (Earwigs) (Fig. 2(L)), as well as the minor groups, such as Zoraptera (Groundlice) (Fig. 2(M)), Mantophasmatodea (Heelwalkers), and Grylloblattodea (Ice Crawlers) show an almost typical insect sperm. Mantodea (Praying Mantises) sperm are characterized by a flagellar axoneme with an extended intertubular material (Fig. 2(N)); Phasmatodea (Stick Insects), except for the basal *Timema poppensis*, which retains a typical insect sperm (Fig. 2(O)), have a flagellum without mitochondrial derivatives, substituted by two elongated, crystalline accessory bodies. Isoptera (Termites), which are a subordinate group of Blattodea, with the exception of the multiflagellated sperm of *Mastotermes darwiniensis*, exhibit aflagellated immotile sperm (Fig. 2(P)). Blattodea (Cockroaches) have a conventional insect sperm type (Fig. 2(Q)). Among Acercaria (=Paraneoptera), Thysanoptera (Thrips) have three centrioles at the beginning of spermiogenesis, which give rise to three axonemes (Fig. 2(R)). Later these axonemes fuse and amalgamate to form a single motile flagellum with a microtubular complex consisting of 27 units (Fig. 2(S) and (T)) consisting of doublet and singlet microtubules, without accessory tubules (Fig. 2(S) and (T)). Phthiraptera (Lice), and some species of Psocoptera (Barklice, Booklice) have two flagellar axonemes. Heteroptera (True Bugs), have a conventional insect sperm, often exhibiting a sperm heteromorphism with sperm of different length. Characteristic of their sperm flagellum is the presence of multiple points of crystallization in the matrix of the mitochondrial derivative and the lack of accessory bodies (Fig. 1(G)). Hemiptera, are one of the megadiverse insect lineages: Auchenorrhyncha (Cicadas, Leafhoppers, Spittlebugs, etc.) have a typical sperm pattern in many species, but modifications can occur; in Membracidae and Jassidae the posterior sperm region is flattened and microtubule doublets and accessory tubules are arranged in straight row (Fig. 2(U)). In some genera, the distal part of the flagellum divides into several branches. Sternorrhyncha (Plant Lice, Aphids, Jumping Plant Lice, Whiteflies, Mealybugs and Scale Insects) show an evolutive trend with a progressive involution of the flagellar axoneme, starting from Aphidoidea, provided with a conventional sperm, toward Coccoidea, which have lost the acrosome and the mitochondria, and the sperm flagellum has recovered motility due to the presence of a bundle of singlet microtubules (Fig. 2(V)). Among Holometabola (=Endopterygota), Hymenoptera (Sawflies, Wasps, Ants, Bees) is a large order thought to be the sister group of the rest of the Holometabola orders. (Beutel *et al.*, 2011; Peters *et al.*, 2014). Their sperm structure conforms to the typical pterygote model (Fig. 3(B)). The sperm leave testes in bundles (spermatodesms) as occurs in "Symphyta" (Fig. 3(A)) or may become free as in Apocrita. Sperm association has not been found in parasitic wasps and this character has been retained as an apomorphy, whereas the sperm association in bundle would represent the ancestral condition. Neuropteroida comprises two main groups, Coleoptera and Strepsiptera on one hand, and Neuroptera (Lace Wings), Megaloptera (Alderflies) and Raphidioptera (Camelneck Flies) on the other. Neuropteroida are related to Coleoptera based on the presence of a well-developed accessory bodies and the shape and extension of the intertubular material between accessory tubules in the axoneme (compare Fig. 2(C) and (D)). Strepsiptera sperm are almost typical, as are those of Coleoptera (Beetles), the largest insect order. The two groups are closely related. Within Coleoptera, some families such as Attelabidae and Rhynchitidae share the common flagellar axoneme of 9+9+0 type, while in some species of Ptiliidae the sperm are aflagellated and immotile. In the clerid *Divaes bipustulatus* the mitochondrial derivatives are greatly enlarged, with the sperm becoming giant (Mazzini, 1976). Also Neuroptera exhibit several sperm models. Coniopterygidae have a 9+9+3 axoneme and Mantispidae exhibit both conventional and giant sperm, these latter due to the great size of the mitochondrial derivatives and of the accessory tubules (Fig. 1(O)). Mecoptera (Scorpionflies) (Fig. 3(E)) and Siphonaptera (Fleas) (Fig. 3(F)) are closely related groups showing a simple 9+2 axoneme, as a clearly derived condition by reversal; in the mecopteran *Panorpodes* sp., in fact, the sperm axoneme is a typical 9+9+2. Diptera (Flies) is a large insect order with a great variety of sperm structures dealing in particular with the axoneme. Species of the suborder Nematocera show numerous aberrant models either with regard to the acrosome and the flagellar axoneme. Some basal Keroplatidae and Mycetophilidae have a typical insect sperm axoneme (Fig. 3(G)), but in related families, such as Culicidae, the axoneme has only one central tubule, thus becoming a 9+9+1 model, while in Bibionidae axoneme, the central tubule is missing. Among Psychodidae, Phlebotominae have flagellate motile sperm, but Psychodinae have lost the axoneme and the sperm has become immotile. The large Cecidomyiidae family have the largest

variety of flagellar axoneme described to date. Among some species of Micromyidi the axoneme has the peculiar 10+0 model, as also have the Stomatosematidi; in the Asphondylii and Cecidomyiidi the motile flagellar axoneme has a great number of microtubule doublets (Fig. 3(H)), up to two thousand, with the unique finding among insects to have only the outer dynein arm on each microtubular doublet. The sperm axoneme is reminiscent of one present in the related family Sciaridae. To the contrary, the species of the suborder Brachycera have an almost uniform sperm structure, but the sperm flagellum lacks accessory bodies (Fig. 3(I)). In the Diopsidae sperm, however, a central dense band extends all along the sperm tail. Among Brachycera, *Drosophila bifurca* has the longest sperm described so far. Within the group, a sperm heteromorphism has also been described. The same unexpected sperm difference, is present between the sperm structure of Trichoptera (Caddisflies) and Lepidoptera (Moths and Butterflies). In the former order, the Integripalpia exhibit a few modifications dealing with the presence of only the inner arm on the microtubular doublets and the presence of a single mitochondrial derivative (Fig. 3(J)); the Annulipalpia, instead, have several aberrant immotile sperm. In Polycentropodidae and Philopotamidae the doublets are always without arms and therefore the sperm are immotile (Fig. 3(K)). Hydropsychidae have a bizarre sperm provided with finger-like appendages extruding from the cell body and containing doublet microtubules. In the philopotamid *Chimarra florida* and some species of Hydroptilidae, the axoneme degenerate during spermiogenesis or it is absent and the sperm become immotile (Fig. 3(L)). To the contrary, Lepidoptera have a quite uniform sperm structure, with the main characteristic consisting in the presence of an expanded glycocalyx and the occurrence of two types of sperm: apyrenic and eupyrenic sperm, the former without the nucleus and evident glycocalyx (Fig. 3(M) and (N)). It has been suggested that apyrenic sperm may maximize the first male's fitness by delaying female remating behaviour (Snook, 1997).

A phylogenetic analysis of the whole group has been elaborated based on the several sperm characters described in the insect orders (Dallai *et al.*, 2016b; Gottardo *et al.*, 2016). Sperm characters strongly support the phylogenetic position of several major lineages, for instance Diptera and Insecta, Zygentoma and Pterygota, Psocoptera and Phthiraptera. To the contrary, some clearly related groups, such as Trichoptera and Lepidoptera exhibit a greatly different sperm structure. Some orders, have a very conservative sperm (Heteroptera and Odonata), while others show a highly variable sperm morphology (Diptera).

Spermatogenesis and Spermiogenesis in Crustaceans

Günter Vogt, University of Heidelberg, Heidelberg, Germany

Introduction

Crustaceans are a highly diverse animal group with respect to morphology, physiology, life history, and ecological adaptation. They comprise more than 67,000 species, including water fleas, copepods, ostracods, barnacles, amphipods, isopods, shrimps, lobsters, crayfish, and crabs. Their adult size ranges from 0.1 mm to almost 4 m (leg span) and their maximum age ranges from a few days to more than 70 years. All of the longer-lived crustaceans are iteroparous, i.e., they undergo multiple reproductive cycles over the course of their lifetime. Most species are free living but some are parasitic. Crustaceans occur in a broad variety of marine, limnic and terrestrial habitats from deep sea trenches to high mountain areas and from polar regions to the tropics. Accordingly diverse are their reproductive strategies, sperm types, and fertilization mechanisms (Vogt, 2016). In the following, germ line specification, spermatogenesis, spermiogenesis, sperm structure, and capacitation and activation of the sperm are described for selected taxa, highlighting some peculiarities unique to the Crustacea.

Sperm Types

Most higher taxa of the Crustacea have evolved aflagellate sperm types (Jamieson, 1991). Flagellate spermatozoa are found in a few “lower” crustacean groups (Entomostraca) including the basal Remipedia and the Cirripedia (Fig. 1(A)). The aflagellate spermatozoa are small rods (Fig. 1(B)) and discs of a few micrometer, larger globules with apical spikes or lateral arms (Fig. 1(C)), inverted umbrellas (Fig. 1(D)), or giant filiform tubes up to 1.2 cm in length (Fig. 1(E)). Some crustacean spermatozoa are cytologically very simple, consisting only of the nucleus and a small rim of cytoplasm like in Euphausiacea (krill). Others are highly complex including heterogeneous acrosomes (Fig. 2(E)) like in Decapoda (shrimps, lobsters, crayfish, and crabs) or unique cell organelles like in Ostracoda (mussel shrimps).

Germ Line and Testis Anlage

The primordial germ cells of crustaceans arise either by preformation or epigenesis (Extavour, 2005). Preformation is characterized by the asymmetric localization of maternal factors in the early cleavage stages, which determine the cell lineage that produces the primordial germ cells. Epigenesis describes the determination of germ cells via inductive signals from surrounding tissues later in development. Preformation is probably the plesiomorphic condition in crustaceans. It occurs in taxa associated with total cleavage such as the cladocerans, ostracods, copepods, cirripeds, and amphipods. Epigenesis is the derived condition and is typical of the superficially cleaving “higher” crustaceans (Malacostraca) including the isopods and decapods.

Development of the germ line and formation of the gonad anlage is rather well investigated in the amphipod *Parhyale hawaiiensis*, a crustacean model of development (Extavour, 2005). The germ line originates from a single blastomere of the 8-cell stage, the primordial germ cell (PGC). It is characterized by the RNA helicase Vasa, a general germ line marker of animals. Vasa protein is not required for the generation of the germ cells in the sand hopper but for their proliferation and maintenance. The PGCs multiply during the germ disc stage and are arranged in a row perpendicular to the longitudinal axis in the elongated germ band stage (Fig. 1(F)). At the beginning of limb development, the PGCs separate into right and left clusters and migrate then dorsolaterally. A few days before hatching they reach their final destination on either side of the heart primordium, which forms along the dorsal mid-line of the embryo. Finally, the PGC clusters elongate into rows of cells that extend over two thoracic segments. Together with surrounding soma cells they form the gonad anlage.

Freshwater crayfish are an example of epigenetic germ line determination. During early development, only the cell nuclei multiply and are homogeneously dispersed across the surface of the embryo. Cell membranes are formed from the 256-nuclei stage. It is not yet known when the first PGCs appear but in late embryos there is at least one larger PGC present on each body side underneath the dorsally located heart. Together with a thin layer of surrounding soma cells they form the paired gonad anlage (Taketomi et al., 1996). The gonad is specified as testis or ovary only after hatching. In genetic males, an insulin-like hormone from the androgenic gland induces development of the gonad anlage into a testis and transformation of the PGCs into primary spermatogonia. In the absence of the androgenic hormone, the gonad anlage develops into an ovary (Krol et al., 1992). During the early juvenile stages, the two testis anlagen fuse into a single Y-shaped organ that differentiates into testicular acini and collecting ducts. At the same time, the primary spermatogonia multiply. In the mid-period of juvenile development, spermatocytes and spermatids appear in the seminiferous epithelium of the testicular acini, and the testis becomes linked to the gonopores by paired vasa deferentia. In the final juvenile stages, the lumina of the acini get increasingly filled with spermatozoa.

Spermatogonia and Spermatocytes

The male reproductive system of crustaceans is very variable with respect to shape and components (Krol *et al.*, 1992). However, there are always one or more testes in which the sperm is produced. The most variable parts are the efferent ducts, accessory glands, and copulatory organs. As in most other animals, the testis is subdivided into seminiferous acini or tubules that are lined by a seminiferous epithelium. This epithelium consists of germ cells and soma cells (Fig. 1(G)). The latter are sometimes called Sertoli cells. Like in mammals, the germ cells develop in close association with the Sertoli cells from spermatogonia through spermatocytes and spermatids to spermatozoa. In freshwater crayfish *Procamburus clarkii*, sperm development occurs synchronously within individual seminiferous acini but may differ among neighboring acini (Fig. 1(G)). In the crab *Portunus pelagicus*, each testicular tubule is longitudinally divided into germinal, transformation, and evacuation zones including successive stages of cellular differentiation (Stewart *et al.*, 2010).

The primary spermatogonia function as germ stem cells. They are capable of self-renewal and multiply by mitotic divisions during organogenesis and sperm production. In most longer lived crustaceans, the spermatogonia show alternating periods of activity and quiescence in an annual rhythm. The Sertoli cells obviously play a key role in activation and deactivation of the spermatogonia. In the quiescent testis of freshwater crayfish they surround the spermatogonia almost completely (Fig. 1(H)). In the

It includes a spermatozoon coiled in several spirals (arrows) (Reproduced with permission from Matzke-Karasch, 2005. *Journal of Experimental Zoology Part B* 304, 129–149.).

active testis, cytoplasmic processes of the Sertoli cells are often extremely attenuated, extending between the developing germ cells throughout much of spermatogenesis (Harvey *et al.*, 2001). They apparently have different functions. They provide a scaffold for the developing germ cells, phagocytose excess cytoplasm from the differentiating spermatids, and occlude the adluminal testicular epithelium preventing the spermatids and spermatozoa from contact with hemolymph-borne substances. In mammals, such a blood-testis barrier is more basally located between the spermatogonia. In crayfish, the Sertoli cells additionally secrete the material of the extracellular capsule that encloses each spermatozoon (Fig. 2(E)).

The spermatogonia give rise to spermatocytes that undergo meiosis and subsequently differentiate into spermatids. Depending on species, one or two spermatogonial stages and several spermatocyte and spermatid stages are discernible on the basis of morphological criteria. For example, in the shrimp *Penaeus monodon* two types of spermatogonia, five stages of spermatocytes, and six stages of spermatids have been distinguished (Feng *et al.*, 2017). Spermatogonia A are located on the basal lamina of the seminiferous tubules and give rise to smaller spermatogonia B with higher proportions of euchromatin. Spermatogonia B divide mitotically into primary spermatocytes that remain interconnected by cytoplasmic bridges and undergo meiosis. Therefore, the most conspicuous cytological alterations during spermatogenesis concern the nucleus and chromatin. The spermatocyte stages are subdivided according to the meiotic stages leptotene, zygotene, pachytene, diplotene (Fig. 2(A)), and diakinesis.

Meiosis is a key process in gamete production of all animals. It is a specialized cell division program that consists of a single round of DNA replication followed by two consecutive rounds of cell division thereby forming haploid gametes from diploid germ cells. Although meiosis is conserved across animals, there are substantial differences in timing and regulation of the various steps. Immunostaining of the testis of water flea *Daphnia magna* with antibodies against key proteins of meiosis revealed differences to other arthropods with respect to early recombination (Gómez *et al.*, 2016). There were also differences in epigenetic histone modifications throughout spermiogenesis. In water fleas taken from a natural population, chromosomal aberrations occurred in all meiotic stages amounting to 8.8%, 6.2%, 12.4% and 10.6% in metaphase I, telophase I, metaphase II and telophase II, respectively. In inbred lineages, the respective values were much higher.

Spermatids and Spermatophores

Spermiogenesis is characterized by the progressive differentiation of the germ cells. Some processes of spermiogenesis such as cytoplasm reduction and chromatin decondensation are shared by most crustaceans but others are taxon specific, depending on whether flagellae, acrosomes, or special cell organelles are produced. Mitochondria, endoplasmic reticulum, and Golgi bodies are present in spermatogonia (Fig. 1(G)), spermatocytes, and spermatids (Fig. 2(B) and (D)) but in the spermatozoa they are often lost. The degradation of these membranous cell organelles leads to the formation of multilamellar bodies (Fig. 2(E)). In flagellate sperm, formation of the axoneme dominates spermiogenesis. An example is the barnacle *Amphibalanus amphitrite* in which the axoneme is closely apposed to the nucleus. Early and mid-spermatids include numerous microtubules that form the axoneme and plenty of ribosomes, rough endoplasmic reticulum, and Golgi bodies (Fig. 2(B)) that are required to produce the proteins of the axoneme and the acrosome.

Acrosome formation is the most conspicuous feature in spermatids of decapods (Stewart *et al.*, 2010). An example is the shrimp *Penaeus monodon*, which shows six stages of spermiogenesis (Feng *et al.*, 2017). In stages 1–3, the acrosomal vesicle is formed and enlarged, and in stage 4, an electron-dense body appears in the anterior part of the acrosome (Fig. 2(C)). In stages 5 and 6, the nuclear envelope disintegrates and a spiky structure emerges from the acrosome. The following spermatozoal stage is characterized by a protruding apical acrosome, a subacrosomal chamber, and a basally located nucleus with decondensed chromatin (Fig. 2(C), inset).

The spermatids of barnacles and freshwater ostracods are characterized by the development of special organelles. Barnacle spermatids produce very large accessory bodies (Fig. 1(A)) of unknown function that disappear shortly before fertilization. Ostracod spermatids synthesize paired feather-like organelles and rod-like mitochondrial derivatives of considerable length (Fig. 2(D)). These organelles facilitate motility of the aflagellate sperm during fertilization. The paired mitochondrial derivatives originate from the fusion of small mitochondria at the beginning of spermiogenesis. The mitochondrial cristae are then reorganized around a central paracrystalline matrix. The feather-like organelles originate from membranes of the nucleus, the endoplasmic reticulum, and Golgi vesicles. As soon as the construction of the feather-like organelles is finished, the endoplasmic reticulum and the microtubules disappear.

The biochemistry and molecular biology of spermiogenesis in crustaceans is only poorly investigated. An example is the expression of a novel protein named EsSoxB2–1 in crab *Eriocheir sinensis*. This protein is essential for maturation of the nucleus in the spermatozoa as demonstrated with knockouts (Liu *et al.*, 2016). During fertilization it is delivered to the oocyte together with the chromatin and may act as a paternal transcription factor during early embryonic development. Another interesting example is the reduction of most histones in the decondensing nuclei of crab spermatids, with only small amounts of histones H2B and H3 remaining in the mature spermatozoa (Stewart *et al.*, 2010). Chromatin decondensation is shared by most decapods. This feature stands in sharp contrast to chromatin condensation in the mammalian spermatids, which is mediated by small basic proteins called protamines. An exception to the rule in crustaceans are the freshwater ostracods in which the nucleus becomes heterogeneous during spermiogenesis (Fig. 2(D)), including electron-dense clumps, fibrillar material, and an axial rod.

In most crustaceans, the spermatozoa are enclosed in spermatophores (Fig. 2(E)) that are produced and accumulated in the vas deferens. In freshwater crayfish, hundreds of spermatozoa are packaged in a spermatophore (Niksirat *et al.*, 2016). The different layers of the spermatophore wall are synthesized in different sectors of the vas deferens by secretory epithelial cells. In fish lice (Branchiura), the spermatophore material is produced in specific prostate glands and then delivered to the vas deferens. In the giant sperm producing freshwater ostracods, the spermatozoa are not enclosed in spermatophores. Their paired vasa deferentia include voluminous seminal vesicles and large, complicated sperm pumps (Matzke-Karasz *et al.*, 2017). The seminal vesicles serve for sperm accumulation and maturation and the sperm pumps for ejection of individual spermatozoa during copulation. They consist of flexible chitinous elements and interspersed musculature. In many decapods, ejaculation of sperm from the vas deferens can be artificially elicited by electrical stimuli, which is a convenient non-invasive method for sampling of sperm for experimentation.

Capacitation and Fertilization

Crustacean males do not release their sperm into the water as is the case in many other aquatic invertebrates. They rather transfer the sperm to the females for storage until oviposition. The sperm is usually transmitted by a penis or a secondary copulatory organ that

takes the sperm from the gonopores. It is either externally attached to the females as spermatophore clump or deposited within female sperm receptacles. Even the flagellate sperm of the sessile barnacles is transferred with a penis, which is unique in sedentary animals. As a result, cirriped penises are the longest copulatory organs relative to body length in the animal kingdom (Vogt, 2016).

In the female storage site the spermatozoa undergo further modification, which is called capacitation. In signal crayfish *Pacifastacus leniusculus*, these modifications include structural changes of the acrosome, the subacrosomal area and the chromatin, alterations of protein expression, and changes of the tyrosine phosphorylation pattern along the radial arms (Niksirat *et al.*, 2016). In penaeid shrimps, capacitation mainly concerns changes of the acrosome. In vitro assays with *Litopenaeus occidentalis* revealed that acrosome reactivity is significantly higher in sperm removed from the female storage site than in sperm taken from the male, indicating that post-testicular modifications are essential to obtain full fertility (Alfaro *et al.*, 2007). This information is important to develop in vitro fertilization techniques for shrimp aquaculture.

Fertilization of the eggs occurs either in sea water by the simultaneous release of eggs and stored sperm from the females (e.g., penaeid shrimps), in the female genital tract (e.g., brachyuran crabs) or in special transient compartments like the fertilization tent of freshwater crayfish. This unique gelatinous structure is produced at the underside of the females shortly before spawning and provides the special conditions required for activation of the spermatozoa and eggs (Vogt, 2016). The spermatozoa of most crustaceans are apparently activated by dissolution of the surrounding spermatophore material. In contrast, the giant sperm of ostracods are activated by disintegration of the outer sperm coat (Matzke-Karasz *et al.*, 2017). In the shrimp *Rhynchocinetes typus* unfolding of the stellate arms (Fig. 1(D)) is triggered by contact with sea water.

During fertilization the spermatozoa enter the ooplasm either partly or completely, depending on taxon. Examples of the former variant are the reptantian decapods, and examples of the latter variant are palaemonid shrimps (Fig. 2(F)) and ostracods (Fig. 2(G)). Curiously, the giant spermatozoa of freshwater ostracods enter the oocytes completely although they are several times longer than the eggs. The volume of the internalized sperm is about 0.5–1% of the volume of the corresponding egg, depending on species. The sperm constituents are dissolved before the 32-cell blastula.

The spermatozoa of some crustaceans, for example, palaemonid shrimps and freshwater ostracods, have no acrosome. Penetration of the egg envelope is therefore assumed to occur mainly mechanically (Fig. 2(F)). However, lytic enzymes bound to the apical cell membrane of the sperm may aid penetration. In contrast, in penaeid shrimps, invasion of the egg envelope is chemically mediated by a trypsin-like lysin and further enzymes from the acrosome (Chen *et al.*, 1994). A special case is the “explosion sperm” of reptantian decapods. Upon contact with the oocyte their large acrosome is abruptly everted, generating a forward directed mechanical force that “shoots” the sperm into the egg envelope (Talbot *et al.*, 1991). Concomitantly, the nucleus is torn from basal to apical facilitating fusion with the oolemma. Apparently, only the nucleus and a small acrosomal filament enter the ooplasm whilst the other parts of the sperm remain outside.

The duration of fertilization in crustaceans is variable. In the shrimp *Rhynchocinetes typus* it lasts about 45–60 min. Monospermy seems to be the rule but polyspermy may occur in some shrimps (Fig. 1(D)). In the crab *Maja squinado*, hyperpolarization of the egg membrane in response to fertilization was shown to constitute an electrical block to polyspermy.

Many crustacean females are promiscuous and store sperm from more than one male in their sperm receptacles, enhancing the genetic variability of the offspring (Vogt, 2016). The maximum number of fathers per clutch reported so far is 11 in the shrimp *Caridina ensifera*. In some brachyuran crabs, sperm can be stored and nourished for years in the female receptacles. This sperm largely retains viability and can be utilized for multiple fertilizations. For example, females of Tanner crab *Chionoecetes bairdi* isolated from males after copulation produced viable eggs by 100% in the mating year and 97% and 71% in the following two years. Long-term sperm storage enables posthumous paternity, the ongoing siring of offspring after the death of the sperm provider. This phenomenon may be of some relevance in male-based crab fisheries, in which the largest (i.e., oldest) specimens are regularly removed from the population.

Glossary

Acrosome Membrane-bound vesicle in the head of a spermatozoon, usually anterior to the nucleus, that enables the sperm to penetrate the egg coat and enter the egg for fertilization.

Aquasperm Morphologically simple sperm that are released into the water column.

Axoneme The central structure of a cilium or flagellum composed of microtubules held together by cross-bridges. The microtubules are usually arranged as a ring of nine outer pairs (doublets) and a central pair of single microtubules.

Chromatin Material in the nucleus consisting of protein, DNA and RNA.

Cisternae Membranous plates or discs of some cell organelles. In the Golgi body they are arranged as a stack of membranous discs.

Cristae Infoldings of the inner membrane of the mitochondrion.

Euspermatozoon Fertilizing spermatozoon.

Heterochromatin A tightly packed form of chromatin. When viewed with a transmission electron microscope it is more densely stained.

Introsperm Morphologically more complex spermatozoa produced by animals with internal fertilization.

Mid-piece Region of a spermatozoon that includes the mitochondria and centrioles or centriolar complex from which the axoneme of the tail originates.

Paraspermatozoon Non-fertilizing cells produced in the testis.

Synaptonemal complex A large proteinaceous structure that assembles at the interface between aligned homologous chromosomes during meiotic prophase and holds the chromosomes together.

Taxon (plural taxa) Any unit (division) used in biological classification.

Introduction

The Mollusca is the second most diverse animal phylum with over 100,000 species. The phylum contains many well-known organisms including clams, mussels, snails, squids and octopuses. Molluscs are found in almost every ecosystem in the world from the Arctic to the Antarctic, as well as the deep sea, lakes, rivers, and mountain ranges. There are currently seven classes of mollusc recognized (Aplacophora, Monoplacophora, Polyplacophora, Bivalvia, Gastropoda, Scaphopoda, Cephalopoda) and nearly all species within these taxa reproduce sexually, a process that requires males to produce spermatozoa. The form (structure) of spermatozoa within the Mollusca is very diverse. In species where sperm and eggs are released into the water column for fertilization to occur (external fertilization), the spermatozoa (categorized as aquasperm) are relatively small, usually between 50 and 90 μm long, and simple in structure. By contrast, in species with internal fertilization (i.e., fertilization within the female reproductive tract) the spermatozoa (categorized as introsperm) are usually larger ($>130 \mu\text{m}$ long and up to 1.8 mm long in some pulmonate snails), are highly modified, and therefore structurally more complex. It is therefore not surprising that many of the structural changes that take place during spermatogenesis of these two categories of spermatozoa are different.

Spermatozoon formation is even more varied in some taxa with internal fertilization because males produce more than one type of spermatozoon in their testis. In addition to fertilizing spermatozoa (euspermatozoa), such males also produce non-fertilizing sperm (paraspermatozoa) (sperm terminology after [Healy and Jamieson \(1981\)](#)). The production of dimorphic or polymorphic spermatozoa has been reported for taxa within the class Gastropoda (many Caenogastropoda, Neritimorpha, and Skeneidae) and some species within the bivalve families Galeommatoidea, Lucinacea, Leptonacea and Corbiculacea. The diversity of spermatozoa and spermatogenesis has been used to provide characters in many taxonomic and phylogenetic studies.

Because there are important morphological and cytological differences during spermatogenesis of eusperm and parasperm, their formation will be considered separately.

Spermatogenesis – Euspermatozoa

The testis of molluscs is compartmentalized either as a series of lobular structures (acini) or tubes within which spermatogenesis occurs. The early stages of development are always located close to the wall of the compartments with progressively more developed stages closer to the lumen of each acinus or tube. Spermatogenesis can be divided into four developmental stages: (i) production of spermatogonia from germ cells; (ii) proliferation of spermatogonia by mitosis; (iii) formation of spermatocytes by meiosis; and (iv) spermiogenesis – the development of spermatids into spermatozoa. During cell division (stages ii and iii) cytoplasmic separation

(cytokinesis) is not complete. Therefore, throughout spermatogenesis groups of developing spermatozoa are connected as a syncytium by cytoplasmic bridges (**Fig. 1(C)**), the number of spermatozoa per group depending on how many mitotic divisions occurred during proliferation of the spermatogonia (stage i). For example, in some gastropods the original spermatogonium may divide to produce 32 primary spermatogonia that divide to form 64 secondary spermatogonia. After the two meiotic division of the spermatocytes, 256 haploid spermatids are produced. The cytoplasmic connections are eventually severed by cytokinesis late in spermiogenesis.

The structural features of spermatogonia, spermatocytes and spermatids, and morphological changes that occur during development have been described by light and electron microscopy for examples of all higher molluscan taxa. Up until spermiogenesis, the structural features of spermatogonia and spermatocytes, as seen with a transmission electron microscope, are very similar in all molluscs. Spermatogonia are roughly spherical to pyriform in shape with a central spherical nucleus (with patchy heterochromatin) containing one or two nucleoli surrounded by a relatively small amount of cytoplasm. The cytoplasm contains small rounded to oblong mitochondria (when seen in cross section), ribosomes and some endoplasmic reticula (**Fig. 1(A)**). Spermatocytes have a similar shape to spermatogonia but are usually larger owing to an increase in cytoplasmic volume. In primary spermatocytes the nucleolus disappears and the nucleus, which is often larger than that of spermatogonia, develops synaptonemal complexes during the zygotene and pachytene stages of meiosis (**Fig. 1(B)**). In the cytoplasm the mitochondria may increase in size and a Golgi body with several cisternae is conspicuous as well as two centrioles. After the first meiotic division the secondary spermatocytes and their nuclei are usually smaller, whereas the Golgi body may be more developed. In some species

Fig. 1 Diagrammatic representation (interpreted from transmission electron microscope images) of spermatogenesis in molluscan aquasperm. A, Spermatogonium with spherical nucleus (N) containing a nucleolus (Nu). B, Spermatocyte with synaptonemal complexes (Sy) present in nucleus. Note also the presence of a short flagellum (F) and proacrosomal vesicles (PAV) indicating the first phase in acrosome formation. C, Early spermatids joined by cytoplasmic bridges (arrow). At this stage the nucleus of the spermatids is characterized by a patchwork of heterochromatin. D, Mid-spermatid showing fine granular phase of chromatin condensation. E, Late spermatid showing coarse granular phase of chromatin condensation and acrosomal vesicle (AV) positioned anteriorly. F, Spermatozoon in which the chromatin is completely condensed. AV, acrosomal vesicle; CE, centriole; DC, distal centriole; ER, endoplasmic reticulum; F, flagellum; G, Golgi body; M, mitochondrion; N, nucleus; PAV, proacrosomal vesicle; PC, proximal centriole. Arrow, cytoplasmic bridge. Not drawn exactly to scale.

the cytoplasm of spermatocytes develops small membrane-bound electron-dense vesicles. These vesicles, which appear to be produced by the Golgi body and possibly the rough endoplasmic reticulum, are the precursors of acrosomal vesicles. In addition, a small flagellum may be present (Fig. 1(B)) but this is resorbed prior to spermiogenesis.

The greatest changes, morphological and cytochemical, take place during spermiogenesis, the transformation of spermatids into spermatozoa in which three structural regions (head, mid-piece and tail) are recognized.

Spermiogenesis of Aquasperm

Aquasperm are produced by scaphopods, monoplacophorans, the chaetoderms (Aplacophora), and the majority of bivalves, chitons, patellogastropods and vetigastropods. The early spermatids of aquasperm have a relatively small spherical nucleus that contains a patchwork of heterochromatin (Fig. 1(C)). Early in spermiogenesis the chromatin becomes homogeneously distributed within the nucleus and takes on a fine granular appearance (Fig. 1(D)). The granules are about 20 nm in diameter and this change in chromatin appearance has signalled a transition in proteins associated with the DNA of the nucleus. Up until the early spermatid stage the DNA is associated with histones and these are gradually replaced with protamines that are sperm nuclear basic proteins (Chiva *et al.*, 2011). This change in nuclear proteins is necessary for chromatin condensation and a major change in shape of the nucleus. Within the cytoplasm of early spermatids, mitochondria surround the nucleus, a flagellum begins to form from one of the centrioles, and a Golgi body is present. In species where proacrosomal vesicles have not formed in spermatocytes, these now appear (Fig. 1(C)) although in some species a larger single proacrosomal vesicle develops from Golgi secretions. As the spermatid matures the chromatin in the nucleus further condenses because the granules become reorganized as coarse granules often about 60 nm in diameter (Fig. 1(E)). These larger granules are brought about by further substitution of histones by protamine (Chiva *et al.*, 2011). Therefore, the nucleus is now mainly composed of DNA and protamine. In the final stage of spermiogenesis the coarse granules usually coalesce into the fully condensed form of the nucleus of the mature spermatozoon (Fig. 1(F)). This process is brought about by the protamine being chemically dephosphorylated. In chitons, however, the chromatin becomes twisted into fibres before final condensation. The process of chromatin condensation usually results in a gradual change in shape of the nucleus. Whilst the nucleus may remain more or less spherical in some species, in others it becomes cylindrical, conical or bullet-shaped.

During spermiogenesis the acrosome develops from either the single proacrosomal vesicle, or more usually by fusion of the small proacrosomal vesicles into a single vesicle. An exception to this is found in the bivalve families Trigonoidea and Unionoidea where the vesicles do not fuse, the acrosomal complex of the mature spermatozoon consisting of several anteriorly positioned vesicles (Healy, 1989). In most species the acrosome forms in the presumptive posterior region of the spermatozoon. As the spermatid matures and changes shape, the developing acrosome migrates to the anterior pole of the nucleus (Fig. 1(E)) where it assumes its final form often becoming cap-shaped or conical (Fig. 1(F)). This can involve elongation and differentiation of the acrosomal contents, as well as the development of a posterior invagination that creates a subacrosomal space filled with fine granular or fibrillar material. An exception to where the acrosome develops is found in the bivalve group Anomalodesmata. In these bivalves the acrosome forms anteriorly then migrates to the posterior of the late spermatid to become located within the mid-piece (Healy *et al.*, 2008).

As the nucleus matures and changes shape, the amount of cytoplasm in the spermatid decreases and the mitochondria begin to fuse together. This results in an increase in their size and a decrease in their number to between four and seven. As this happens the fusing mitochondria along with the pair of centrioles migrate to the future posterior pole of the nucleus (Fig. 1(D)). Here the larger spherical to oval mitochondria, which have well developed cristae, surround the orthogonally arranged centrioles in tight proximity to the nucleus to form the developing mid-piece of the spermatid. One centriole (the proximal) becomes anchored in a small depression of the nucleus (posterior nuclear fossa), whilst the flagellum, which has the normal 9+2 arrangement of microtubules, continues to develop from the distal centriole to form the tail.

Spermiogenesis of Introsperm

Introsperm are produced by all cephalopods, the neomenioids (Aplacophora), a few bivalves, and many groups of gastropods including the caenogastropods, opisthobranchs and pulmonates. The introsperm of molluscs are extremely variable and more complex in structure with a variety of modifications to the head, mid-piece and tail regions. The morphological changes that occur during spermiogenesis, therefore, reflect this variability. Early spermatids, like those of aquasperm, tend to have a spherical nucleus with a patchwork of heterochromatin (Fig. 2(A)), and during this stage electron-dense material called plaques may form at the future posterior pole or anterior and posterior poles of the nuclear surface. The anterior plaque is usually composed of a layer of extranuclear material whereas the posterior plaque appears to be caused by thickening of the inner nuclear membrane. In early spermatids the cytoplasm has numerous mitochondria, often more than one Golgi body, well-developed endoplasmic reticulum, and one or two centrioles (some of these features shown in Fig. 2(A) and (B)). As the spermatid matures it elongates during which time the nucleus changes shape, and chromatin condensation proceeds.

In the decapod cephalopods (cuttlefish and squids) there is a granular phase of chromatin condensation (Fig. 2(B)) similar to that described for the early spermatids of aquasperm. The 20 nm granules become homogeneously distributed throughout the nucleus. As the spermatid matures, these chromatin granules are transformed structurally and biochemically. The granules are remodelled into thin fibres (about 35 nm diameter) with an antero-posterior orientation (Fig. 2(D)) that contain hyperacetylated histones and a protamine precursor (Chiva *et al.*, 2011). Fibre thickness then increases to about 50 nm in diameter with an increase in protamine precursor and a decrease in the hyperacetylated histone. Finally the thicker fibres coalesce that results in a uniformly electron-dense nucleus, and at this stage protamine is now associated with the DNA. In octopod cephalopods the nuclear protein

Fig. 2 Diagrammatic representation (interpreted from transmission electron microscope images) of some stages of introsperm spermiogenesis in some molluscan taxa. A, Early spermatids showing nuclei with patchwork of chromatin. B and C, Mid-spermatids in which chromatin is becoming granular. Note developing polarity of cell with the acrosomal vesicle (AV) positioned at the anterior pole. D, Late spermatid with fibrous chromatin in the nucleus. Note the microtubules (MT) surrounding the nucleus. E, Mid-spermatid with chromatin condensation beginning at the periphery of the nucleus. The nucleus has also invaginated posteriorly to form the posterior nucleus fossa that houses the centriolar complex (CE). F, Late spermatid with elongating nucleus and mid-piece. The chromatin is now fibrous in appearance and nucleus has invaginated completely to form a central canal that houses the centriolar complex (CE) and axoneme (AX). Ultrastructure of spermatozoa and spermiogenesis in *Spirula spirula* (L.): Systematic importance and comparison with other cephalopods. *Helgoländer Meeresuntersuchungen* 44, 109–123); E and F: a caenogastropod (modified from Buckland-Nicks, J., Williams, D., Chia, F.-S., Fontaine, A., 1983. Studies on the polymorphic spermatozoa of a marine snail. 2. Genesis of the eupyrene sperm. *Gamete Research* 7, 19–37); G–J: a pulmonate gastropod (modified from Healy, J., 2001. Spermatogenesis and oogenesis. In: Barker, G.M. (ed.), *The Biology of Terrestrial Molluscs*. Oxon: CABI Publishing, pp. 357–382).

transition during spermiogenesis is similar to that of decapods, but chromatin condensation is somewhat different in that it begins at the polar regions (developing anterior and posterior of sperm) of the nucleus rather than simultaneously throughout. Chromatin condensation then progressively spreads out throughout the nucleus. In many caenogastropods, after the fine granular phase, chromatin condensation first occurs at the periphery of the nucleus (Fig. 2(E)), spreading inward, whereas in pulmonates, chromatin condensation occurs uniformly throughout the nucleus. This is then followed by the fibrillar phase (Fig. 2(F) and (G)) during which time the histones are gradually and continuously being transformed through a series of protamine precursors into protamines (Chiva *et al.*, 2011). The final phase of chromatin change involves a lamellar phase, the lamellae eventually coalescing to result in the uniformly electron-dense nucleus.

During chromatin condensation the change in nuclear shape of introsperm can be profound. Shape change first begins with the nucleus invaginating posteriorly to form what will become the implantation fossa for the centriole(s) or centriolar derivative (Fig. 2(C)–(H)). In some caenogastropods the elongating spermatid nucleus develops as a long tube because of the formation of a central intranuclear canal (Fig. 2(F)). This is brought about by the gradual deepening of the implantation fossa. As the fossa deepens the centriole(s) or centriolar derivative migrate into the canal along with the axoneme which therefore penetrates the length of the nucleus (Fig. 2(F)). In other gastropods such as the opisthobranchs, pulmonates, and some cephalopods, the nucleus of later spermatids undergoes some torsion (Fig. 2(H)), becoming helical or helically keeled.

The development of the acrosome begins in early spermatids often after polarity of the nucleus has been established. In the Neritimorpha (Gastropoda), acrosome formation begins with the production of several small membrane-bound, electron-dense proacrosomal vesicles by the basally located Golgi body. In most other taxa the Golgi complex or complexes secrete a single proacrosomal vesicle (Fig. 2(A)). As the spermatid matures, the vesicle migrates anteriorly and becomes positioned in the middle of the anterior nuclear plaque. In caenogastropods vesicle migration is often accompanied by the Golgi body which continues to produce material for the developing acrosome (Fig. 2(E) and (F)). The Golgi body may also be associated with endoplasmic reticulum. During migration of the acrosomal vesicle it usually acquires extravesicular material and structures that eventually form subvesicular material, a basal plate, or a pedestal between the acrosome and the nucleus (Fig. 2(E)–(H)).

The mid-piece of molluscan introsperm with its centriole, centrioles, or centriolar derivative and mitochondria varies in complexity and therefore structural changes during spermiogenesis are also highly variable. In cephalopods other than the Octopoda numerous small unmodified mitochondria congregate at the developing posterior end of the nucleus of mid to late spermatids to become located within a cell membrane spur or sheath that is adjacent to, or surrounds, the anterior section of the tail (Fig. 2(C) and (D)). In the mid-spermatids of octopods mitochondrial fusion occurs as the mitochondria become arranged around the axoneme at the base of the nucleus. In the mid to late spermatids of caenogastropods the mitochondria also begin to accumulate at the basal region of the nucleus (Fig. 2(E)) where they fuse (Fig. 2(F)) to form modified mitochondrial elements that vary in number, length and internal structural complexity among taxa. As the spermatid and its axoneme elongates, the mitochondrial elements surround and extend along the axoneme. In some species the mitochondrial elements of the mid-spermatid begin form a loose spiral around the axoneme and by the late spermatid stage they are arranged as continuous helical elements. As the mitochondria fuse the cristae may form a continuous membrane or become transformed into plate-like structures.

In higher gastropods, such as pulmonates and opisthobranchs, as spermiogenesis proceeds the axoneme continues to elongate and the small mitochondria migrate posteriorly where they cluster along the axoneme where they begin to fuse (Fig. 2(G) and (I)). At the same time, nine course fibres of unknown origin become associated with, and surround, the axoneme (Fig. 2(I) and (J)). As the spermatid matures the mitochondria continue to fuse and become wrapped around the axoneme as a sheath (Fig. 2(I) and (J)). As wrapping progresses the mitochondrial material is transformed and by the late spermatid is organized as circular parallel layers of paracrystalline matrix material into what is referred to as a mitochondrial derivative that spirals along the axoneme (Healy, 2001). During wrapping and transformation one or more tubular channels develop within the mitochondrial derivative. In the mature sperm these channels acquire glycogen and they are therefore called glycogen helices (Fig. 2(H) and (J)). Glycogen is a feature of the spermatozoa of many molluscs. This storage product usually appears late in spermiogenesis. It is often deposited intra-axonemally and in addition a section of the axoneme (often the posterior section) of the late spermatids of caenogastropods and opisthobranchs becomes surrounded by glycogen to form a region called the glycogen piece. To date the mechanism of uptake of glycogen into spermatids has not been explained.

A feature of late spermiogenesis of many molluscan taxa is elimination of excess cytoplasm from the spermatids nuclear, mid-piece or tail regions. The excess cytoplasm with organelles such as the Golgi body and endoplasmic reticulum may be discarded by cytoplasmic sloughing and/or reduced by autophagy and lysosomal activity. A further feature of late spermiogenesis of cephalopods, some caenogastropods and pulmonates is the development of a ring of microtubules (called a manchette) around the condensing nucleus and/or mid-piece of the spermatid (Fig. 2(C), (D), (H) and (J)). The precise role of the microtubules has not been established, although it has been suggested that in some species they play a role in helping to form the shape of the spermatozoon.

Spermatogenesis – Non-Fertilizing Spermatozoa (Paraspermatozoa)

Paraspermatozoa have a number of possible functions. In some species they are carriers for the fertilizing eusperm, whereas in other species they may have a nutritive role, stimulate motility of eusperm, or prevent the sperm from rival males being deposited into the female reproductive tract. Parasperms are extremely diverse in structure. Some have very little chromatin whereas others have no chromatin at all. Many are multiflagellate, whilst some lack flagella. Therefore, the morphological changes that occur during paraspermatogenesis reflect these profound structural differences.

Paraspermatogenesis usually occurs at the same time as euspermatogenesis either in the same or specific areas of the testis. Paraspermatogenesis, however, is characterized by atypical meiosis with the primary spermatocyte developing without a maturation division (see [Hodgson \(1997\)](#) for literature review). Paraspermatogonia ([Fig. 3\(A\)](#)) are similar in ultrastructure to the spermatogonia that produce fertilizing euspermatozoa although in some species the round to oval nucleus has distinctive heterochromatin distribution and the cytoplasm often contains well-developed granular endoplasmic reticulum swollen with secretions ([Buckland-Nicks and Tompkins, 2005](#)), and an abundance of mitochondria. Paraspermatocytes, groups of which are joined by cytoplasmic bridges, are readily identified by their relatively large lobulated nucleus and a cytoplasm with several Golgi bodies, numerous mitochondria, extensive granular endoplasmic reticulum, and some electron-dense bodies ([Fig. 3\(B\)](#)). A further feature of many paraspermatogonia and/or paraspermatocytes is the development of a centrosphere ([Fig. 3\(B\)](#)). This consists of a pair of parent centrioles around which satellite centrioles, termed procentrioles, develop. The number of procentrioles vary between and within species. During paraspermiogenesis the procentrioles migrate to the presumptive posterior pole of the developing paraspermatocyte and paraspermatid ([Fig. 3\(C\)](#)) where they become attached to the cell membrane by fibrogranular material. Each procentriole gives rise to an axoneme with a 9+2 arrangement of microtubules, a process known as flagellogenesis. The elongating axonemes may develop entirely within the body of the paraspermatid, or extend as free flagella in the form of a tail brush ([Fig. 3\(D\) and \(E\)](#)). In developing aflagellate parasperm, the centrioles (and therefore the centrosphere) are not present.

The greatest changes in cell morphology occur during paraspermiogenesis. In parasperm that lose most or all of their nuclear material, this often begins with the nucleus fragmenting into several smaller membrane-bound structures that have been termed caryomerites ([Fig. 3\(D\)](#)), each containing some genetic material. At this time lysosomes generated by the Golgi body and rough endoplasmic reticulum accumulate in the cytoplasm. As the paraspermatid matures and in many cases elongates, the chromatin material in each caryomerite first condenses before it degenerates to a mucus-like substance that may be discharged from the cell by exocytosis ([Fig. 3\(C\)–\(E\)](#)). In the lancet parasperm of the marine snail *Fusitriton oregonensis*, however, this material is retained. In other marine snail species (e.g. *Littoraria* spp. and *Cerithidea* spp.) the nucleus does not fragment but gradually decreases in size to leave a nuclear remnant that eventually forms a central core within the parasperm ([Fig. 3\(E\) and \(F\)](#); [Buckland-Nicks et al., 2000](#); [Buckland-Nicks and Hodgson, 2005](#)). The use of Hoechst's DNA stain has shown that the nuclear remnant retains fragments of DNA. The detailed study of [Buckland-Nicks and Tompkins \(2005\)](#) revealed that nuclear breakdown (partial or complete) involves programmed nuclear death (apoptosis) in which lysosomes secreted by Golgi bodies play an important role.

An unusual feature of the paraspermatids of the caenogastropod group Cerithioidea is the formation of what is thought to be an acrosome with a basal plate. These structures form in the presumptive posterior of the early paraspermatid next to the Golgi body, eventually migrating to the anterior of the nuclear remnant ([Fig. 3\(C\), \(E\) and \(F\)](#)). The function of this 'acrosome' in a cell that does not participate in fertilization is not known.

As previously mentioned, the centrioles of flagellated paraspermatids that are attached to the cell membrane function as basal bodies and are the sites of flagella formation ([Fig. 3\(C\)](#)). In parasperm that keep a nuclear core, the basal bodies break away from the cell membrane of the maturing paraspermatids and become attached to nuclear remnant ([Fig. 3\(E\)](#)). In parasperm that lose all the nuclear material the basal bodies may migrate through the cytoplasm as the paraspermatid elongates, ending up at the anterior of the cell where they usually become embedded in a cap-like structure ([Fig. 3\(D\)](#)). During paraspermatid elongation the mitochondria accumulate posteriorly between the axonemes ([Fig. 3\(C\)–\(E\)](#)).

A feature of many parasperm is the presence of numerous, often large, membrane-bound glycoprotein bodies in the cytoplasm as well as glycogen deposits ([Fig. 3\(F\)](#)). The glycoprotein bodies are produced during paraspermiogenesis, probably by the granular endoplasmic reticulum and Golgi bodies. They first appear as small vesicles with an irregular shape ([Fig. 3\(D\)](#)) but then coalesce into larger blocks that surround the axonemes of the flagella. In addition, glycogen is deposited in the final stage of cytodifferentiation, although its origin has not been established. In a few species other cytoplasmic structures form in the cytoplasm of paraspermatids. For example in *Littoraria* spp. (Caenogastropoda) rhomboid granules, which stain positively with RNA stains, arise within rough endoplasmic reticulum cisternae and eventually fuse to form a rod-like body ([Buckland-Nicks et al., 2000](#)).

Seasonality and Endogenous Control of Spermatogenesis

Whilst sperm production can be continuous in some molluscs living in lower latitudes, spermatogenesis in many molluscs can be highly seasonal, especially those living in environments that experience significant seasonal climatic changes. Thus at certain times of the year (e.g., winter in species living at high latitudes) the testis will lack any spermatogenic activity. A number of environmental factors are thought to affect and possibly stimulate spermatogenesis, including temperature change, rainfall or degree of moisture (especially for land snails living in arid environments), photoperiod, and food. Such exogenous factors must stimulate endogenous control of spermatogenesis. Relatively little, however, is known about the endocrine control of spermatogenesis. Indications are that hormones that either inhibit or promote spermatogenesis are produced by neurosecretory cells in the head tentacles and/or cerebral ganglia of some cephalopods and snails. For example removal of the optic glands in octopus resulted in shrinkage of the testis ([Wells and Wells, 1972](#)) and experiments by [Takayanagi and Takeda \(1985\)](#) showed that removal of the optic tentacles of the land snail *Euhadra peliomphala* inhibited spermatogenesis. In this snail injection of optic gland extract stimulated sperm production. Numerous studies have demonstrated the presence of vertebrate-type steroids such as oestradiol, progesterone, and testosterone (all of which play a role in vertebrate reproduction) in molluscan reproductive tissues, with hormonal increase often occurring at the commencement of sperm production. However, the source of these hormones (exogenous or endogenous) and their role is unclear.

Fig. 3 Diagrammatic summary (interpreted from transmission electron microscope images) of some stages of paraspermatogenesis. A. Paraspermatogonium. B. Paraspermatocyte showing centrospheres (CS) and lobulated nucleus (N). Note also the cytoplasmic bridge (arrow). C. Early paraspermatid of a cerithioid snail with nuclear vesicle (NV) and nuclear remnant (NR), Golgi body (G) and adjacent developing acrosome (A). Granular vesicles (GV) are being exocytosed at the posterior of the cell and the centrioles (Ce) are now attached to the cell membrane. D. Mid-paraspermatid in which the nucleus has fragmented into caryomerites (CA) and the basal bodies have migrated through the cytoplasm to the anterior pole with the axonemes. Note the posterior position of the mitochondria (M) between the axonemes. E. Mid-paraspermatid of a cerithioid snail. Note the central nuclear remnant (NR) with ciliary rootlets (CR) attached posteriorly and exocytosis (arrows) of material posteriorly. The acrosome (A) with its basal plate (BP) is now at the developing anterior pole. Also present are fine filamentous (FF) material attached to the cell membrane. F. Mature paraspermatozoon with central nuclear remnant (NR) surrounded by glycogen bodies (GB). GL indicates the position of where glycogen is deposited between the axonemes of the tail brush. A, acrosome; AX, axoneme; BP, basal plate; CE, centriole; CR, ciliary rootlet; CS, centrosphere; G, Golgi body; M, mitochondrion; N, nucleus; NR nuclear remnant; NV, nuclear vesicle; RER, rough endoplasmic reticulum; TB, tail brush. Not drawn exactly to scale. (A),(C),(D)–(F): modified from Buckland-Nicks, J.A., Hodgson, A.N., 2005. Paraspermatogenesis of cerithioid snails: retention of an acrosome and nuclear remnant. *Journal of Morphology* 264, 314–326 and (D) from Buckland-Nicks, J., Williams, D., Chia, F-S., Fontaine, A., 1982. Studies on the polymorphic spermatozoa of a marine snail. 1. Genesis of the aupyrene sperm. *Biology of the Cell* 44, 305–314.

For example Scott (2012, 2013) not only questioned the evidence that such vertebrate-type sex steroids are synthesized by molluscs, but also the role that they play in molluscan reproduction.

Finally, recent studies have begun to identify many of the genes that are involved in euspermatogenesis and associated processes (e.g., see Llera-Herrera *et al.* (2013) and Song *et al.* (2017) for some literature). However, there are no published studies on the genes associated with paraspermatogenesis. Nevertheless, these gene studies will undoubtedly lead to a deeper understanding of the control of spermatogenesis.

Fertilization, Comparative

Introduction

In multicellular metazoan animals, two different types of gametes, eggs and spermatozoa, are unified by fertilization, and as the result fertilized eggs undergo mitotic cell divisions to develop into adult organisms. The processes of fertilization comprise multiple steps with highly sophisticated physical and chemical reactions within each gamete as well as between both gametes, ensuring normal fertilization. In recent years, research in this area has been carried out mainly using mammalian species including the laboratory model animals (e.g., mice and rats), domestic animals (e.g., pigs and cows), and humans. Thanks to that, a comprehensive view of fertilization has begun describing in terms of the cellular and molecular mechanisms. However, it is still worth studying with a wide range of animals to find the general principle as well as some features unique to particular groups or species. In this article, comparative aspects of the fertilization mechanisms in wide range of animal phyla of invertebrates and vertebrates, which could have evolved from a common ancestor ([Fig. 1](#)), are described.

Fig. 1 Example of phylogenetic tree of the multicellular animals described in the text.

The Site of Fertilization

Fertilization occurs inside or outside the females. The site of fertilization is fundamental for determining the animal reproduction modes, oviparity (females lay unfertilized or developing eggs) and viviparity (females retain developing eggs inside their bodies and give birth to their offspring). Thus, all viviparous animals are internal fertilizers, whereas oviparous animals are either internal or external ones. Specifically, a mode in which females lay unfertilized eggs is called ovuliparity.

There are a number of thermic issues regarding the site of fertilization. In general, the site of fertilization does not coincide with the site of sperm deposition (insemination, ejaculation or spawning), therefore spermatozoa must travel in a certain distance to meet eggs. In internal fertilizers, especially in mammals, only a handful number of spermatozoa arrive in the upper (ampullae) part of the oviduct despite hundreds of those can reach the lower (isthmus) part of the oviduct. Several guidance mechanisms, such as thermotaxis, chemotaxis and rheotaxis, have proposed to explain how fertilizing spermatozoa are navigated to the site of fertilization. In the thermotaxis model, a temperature difference between the proximal ampulla and the distal isthmus regulates swimming direction of the ejaculated spermatozoa. Such a temperature difference was actually recorded 0.69°C in pigs and 0.8°C in rabbits. In the sperm chemotaxis model, spermatozoa can sense a gradient of progesterone derived from the cumulus cells surrounding the oocyte and swim toward the source of progesterone. In the rheotaxis model, spermatozoa swim against the fluid flow that is generated from oviduct to uterus after coitus, facilitating sperm guidance over long distances in the female reproductive tract (Miki and Clapham, 2013).

In external fertilizers, gametes are released thereafter diluted into aquatic environment so that timely (synchronous) spawning that increases frequency of sperm-egg encounter could have been developed. In addition, spermatozoa must find conspecific eggs to fertilize them. Hence, species-specificity in sperm-egg interactions, occurring at the level of sperm attraction to eggs, sperm acrosome reaction and sperm binding to the egg surface, are the central issues of research interests for last several decades. Occasionally, timing of sperm deposition (insemination) does not coincide with that of egg deposition (ovulation), therefore spermatozoa must await fertilization in the female reproductive tract, so that research addresses mechanisms of extended sperm survival at molecular, cellular and organismal levels. In many animals, females are promiscuous (polyandry; mating with multiple males), by which postcopulatory sexual selection, i.e., sperm competition and cryptic female choice, can favor fertilizations toward genetically more compatible males. This addresses evolutionary consequences of female reproductive systems and corresponding adaptive sperm traits (Birkhead and Pizzari, 2002).

Most, if not all, species thus far examined that employ external fertilization are cnidarians, echinoderms, ascidians, and teleost fish, whereas most species employing internal fertilization are insects, reptiles, birds, and mammals (both marsupials and eutherians). Mollusks, crustaceans, and amphibians are the groups that employ either internal or external depending on species. In teleost fish, synchronous spawning of gametes from both sexes into the same water column is a common strategy. Both gametes lose their fertilization competence shortly after the spawning, hence fertilization must be completed within a short period of time. Exceptionally, herring gametes, once released into ocean, are still capable of sustaining their fertilizing competence for days and spermatozoa remain quiescence until reached at the egg micropyle region where a sperm motility initiation factor activates spermatozoa and guides the sperm cells into the micropylar canal (Yanagimachi *et al.*, 2017). Sea urchins and starfish employ broadcast spawning where some millions to billions of gametes are released from single adults into sea. Spermatozoa encounter eggs coincidentally or with a chemical cue that guides spermatozoa to a conspecific egg, which is known for sperm chemotaxis. In some corals, spermatozoa and eggs are produced in the same individuals (hermaphrodite) and released together as bundles that drift to the ocean surface where fertilization takes place. Although broadcast spawners release massive amount gametes into sea, synchrony of gamete spawning from both sexes, presumably to gain fertilization opportunities, is a common feature. By contrast, there are some situations where gametes are released asynchronously. For example, in the mediterranean gobies, males deposit spermatozoa in the form of sperm trails laid on the nest surface before females start laying their eggs. To compensate the time-gap between sperm release by males and egg release by females, the sperm longevity (i.e., fertilizability) is guaranteed by either rendering their motility inactive or keeping them active for the extended duration. Several species in jellyfish, ascidians, and teleost fish are taking the former strategy; ejaculated spermatozoa remain quiescent until an egg factor activates sperm motility. Alternatively, spermatozoa are stored quiescently in the female storage organs, such as insect spermatheca, cephalopod or annelid seminal receptacle, bird sperm storage tubules (SSTs), and mammalian sperm reservoir. The average storing period of spermatozoa are varied from one group to another, and even from one species to another; hours to days in mammals, weeks in birds, months in reptiles and cephalopods, years to decades in bees and ants (Birkhead and Møller, 2008). Spermatozoa stored in the female storage organ are thereafter transferred to the site of fertilization. In mammals, fertilization occurs at the outermost portion of the fallopian tube, called the ampulla where ovulated oocytes are picked up by the infundibulum of the oviduct. In birds, spermatozoa in the SSTs at the utero-vaginal junction are transported to the infundibulum through the oviduct. In insects, spermatozoa are stored in spermatheca and fertilization occurs predominantly in the median oviduct. In the squid species, males implant sperm-containing capsules (spermatophores) to the external body surfaces or internal mantle cavities of the females. In some cases, the spermatophores themselves serve as sperm reservoirs, whereas in other cases, spermatozoa released from the spermatophores are stored in the female's seminal receptacles. Although fertilization may take place in the close vicinity of the implanted spermatophores or the seminal receptacles, direct observations are lacking.

Sperm Acrosome Reaction

Mature spermatozoa carry the acrosome, a Golgi-originated single large vesicle within the anterior portion of the sperm head. The acrosomal vesicle is discharged in response to a certain stimulus to release intra-vesicular contents as well as to expose inner surface

of the acrosomal vesicle (inside-out) during fertilization. The anterior tip of sperm head becomes elongated in some marine invertebrates, or sharpened (perforatorium) in mammals following breakdown of the acrosome. Such a series of morphological changes occurring in sperm head is called “the acrosome reaction”. The term “the acrosomal exocytosis” has been often used instead, particularly in mammals. The sperm acrosome reaction has been so far observed in wide range of animal groups such as mollusks (bivalves and sea snails), annelids (polychaete worms), arthropods (shrimps, crabs, and horseshoe crabs), echinoderms (feather stars, starfish, sea cucumbers, brittle stars, and sea urchins), cephalochordates (acorn worms), cyclostomes (hagfish and lampreys), and many other vertebrates including mammals. However, spermatozoa of some groups such as teleost fish lack the acrosome. It is postulated that as egg micropyle has evolved, the acrosome reaction has lost its significance. There are several distinct roles of the acrosome and acrosome reaction for fertilization. In marine invertebrates, the acrosome reaction occurs predominantly during sperm-egg interactions and acrosome-reacted spermatozoa can dissolve the layer covering the egg (egg coat) so that the acrosome reaction is believed to be prerequisite for penetrating the egg coat. The acrosome contains enzymatic activities such as proteases and glycosidases by which spermatozoa may be able to lyse the extracellular matrix of the egg. In sea snails and abalones, however, mode of action of sperm’s lytic activity is non-enzymatic. In sea urchins, the most abundant component of the acrosome is a ~30-kDa protein called bindin that plays the roles in species-specific sperm adhesion to egg surface and sperm-egg fusion. Upon the acrosome reaction, bindin becomes externalized and deposited on the surface of a finger-like protrusion (the acrosomal process) of the sperm head, enabling spermatozoa to attach on the egg vitelline layer (Vacquier, 2012). In mammals, the acrosome reaction is also required for tight adhesion of spermatozoa to the egg coat called zona pellucida and consequently penetration of bound spermatozoa through the zona matrix. Thus, the sperm acrosome reaction must occur at some points before penetrating the egg coat, however the exact location(s) remains unknown. The long-standing hypothesis proposed that acrosome-intact spermatozoa adhere the zona surface thereafter trigger the acrosome reaction. However, acrosome-reacted spermatozoa can also bind the zona and fertilize the egg (La Spina *et al.*, 2016).

In sea urchins, unfertilized eggs are surrounded by a gelatinous transparent layer called jelly coat where spermatozoa undergo the acrosome reaction. Jelly coat contains a sulfated fucose polymer (fucan) that induces the acrosome reaction. In all sea urchin species so far investigated except for one case (a sulfated galactan), egg jelly contains at least one form of sulfated fucans. A structural feature conserved among different sulfated fucans is that they are consisted of tandem repeat of a sulfated oligosaccharide unit (Vilela-Silva *et al.*, 2002). Differences are observed in the glycosidic linkage and positions of sulfation. Such the structural differences can explain the species-specificity in induction of the acrosome reaction. Spermatozoa recognize a conspecific sulfated fucan through a receptor for egg jelly (REJ) located on the flagellar membrane (Gunarathne *et al.*, 2007), which evokes concomitant changes in ionic permeability; the influx of Ca^{2+} and Na^{+} and the efflux of H^{+} and K^{+} . In particular, Ca^{2+} plays an essential role in fusion between the sperm plasma membrane and the outer acrosomal membrane (Gonzalez-Martinez *et al.*, 2001). This fusion event is highly regulated and conserved in the secretory pathway of other cell types (Belmonte *et al.*, 2016). During the acrosomal exocytosis, the membrane dynamics can be divided into several distinctive stages, i.e., priming, docking, fusion, fusion pore opening, vesiculation and shedding. In mammals, fusion pore opening occurs at multiple sites over the acrosome, resulting in massive loss of the plasma membrane overlying the acrosome (shedding of the acrosomal cap).

Sperm-Egg Binding and Fusion

In most animals, the egg plasma membrane is surrounded by a firm membranous acellular structure collectively called the egg coat, or more routinely called vitelline membrane, vitelline coat, vitelline envelope, vitelline layer, chorion, and zona pellucida for specific animal groups. In representative species so far examined, the egg coat is consist of several (glyco)proteins as the major components. The vitelline membrane seems to have essential roles for recognition of spermatozoa from conspecific species to avoid interspecific hybridization, and protection of eggs from microorganisms, mechanical damages and multiple-sperm entry. A fertilizing spermatozoon can penetrate the egg coat at any location in most animal species with a few exceptions such as birds.

In sea urchins, the vitelline layer is very thin and bound tightly to the egg plasma membrane before fertilization. Acrosome-reacted spermatozoa adhere to the vitelline layer in a species-preferential manner via the acrosomal process. Such the species-specific adhesion is mediated by interaction between the complementary molecules called sperm bindin and its receptor, a high molecular weight glycoprotein (approximately 350-kDa) on the egg vitelline layer (Hirohashi *et al.*, 2008). Cross-fertilizations, therefore hybrid embryos, were readily observed when the vitelline membrane is removed by protease treatment, hence the vitelline membrane serves the latest and most potent barrier against interspecific hybridization in sea urchins.

In ascidians, hermaphroditism is common and the level of self-sterility varied. For instance, all species of the families Asciidiidae and Corellidae, and many species of Styela and Molgula are self-fertile, whereas *Ciona intestinalis* and *Halocynthia roretzi* are self-sterile. Such the self-sterility system is accounted for operating at the level of sperm-egg coat interaction because naked eggs exhibit self-fertility. The vitelline membrane of ascidian eggs is present apart from the egg plasma membrane, implying the least involvement of eggs themselves in self/non-self recognition. Thus, the ascidian vitelline membrane is capable of discriminating the spermatozoa from not only foreign species but also same individuals. The molecules responsible for self/non-self recognition, which are easily removed from the vitelline membrane in acid seawater (such as pH 3), have been identified as v-Themis-A/B in *Ciona*. In the current model, it is proposed that when s-Themis-A/B on the sperm surface recognizes self v-Themis-A/B on the vitelline membrane, an intracellular Ca^{2+} rise takes place in the sperm, resulting in the detachment of spermatozoa from the vitelline membrane (Sawada *et al.*, 2014).

Mammalian eggs are surrounded by a thick egg coat called the zona pellucida that contains three (ZP1-3 in mouse) or four (ZP1-4 in human) glycoproteins. It seems that among the glycoproteins, ZP2 is necessary for the binding of spermatozoa to the zona pellucida and that this phenomenon is relatively, but not absolutely, species-specific. Recent analyses using gene-knockout mice have, however, shown that the spermatozoa lacking the zona-binding ability are also able to fertilize eggs in the presence of zona pellucida (Okabe, 2014).

In most species of molluscs including abalones, a vitelline membrane also acts as a barrier against interspecific fertilization, which is regulated by species-specific interaction between a sperm acrosome-derived cationic protein called lysin and its receptor glycoprotein called VERL (vitelline envelope receptor for lysin). Abalone spermatozoa (1 μm in diameter) can make a hole (3 μm in diameter) in the vitelline membrane and penetrate through it. Non-enzymatic action of abalone lysin is presumed to be responsible for such fine regulation. In contrast, it is thought that proteases are used to dissolve the egg coat in deuterostomes such as sea urchins, ascidians, and mammals. In ascidian *Halocynthia*, it is reported that sperm penetration through the egg coat is mediated by the extracellular ubiquitin/proteasome system (UBS), i.e., upon sperm activation, spermatozoa release proteasome, ubiquitin-conjugating enzyme, ubiquitin and ATP into the surrounding seawater. A vitelline coat 70-kDa glycoprotein, HrVC70, which serves as the receptor for sperm binding is subjected to extracellular ubiquitination followed by degradation by the sperm proteasome during fertilization (Sawada *et al.*, 2014). In mammals, extracellular UBS is also suggested to operate during zona lysis. In spite of energetic studies, the proteases responsible for the penetration of zona pellucida have not yet been determined. Since the mouse spermatozoa recovered from the perivitelline space can penetrate through the zona pellucida again (Okabe, 2014), the proteases, if any, are considered to persist on the sperm surface without diffusing after acrosome reaction.

In some animals, a tough and elastic membrane, called chorion, prevents sperm penetration even before fertilization. Alternatively, sperm entry is facilitated by the narrow canal produced in a certain region of chorion, micropyle. A single funnel-shaped micropyle is located near the animal pole in most teleost fish and cephalopod eggs, whereas 4–12 micropyles are present at the animal pole region in the paddlefish *Polyodon spathula*. The number and location of micropyles in insect eggs vary significantly among species. In the fruit fly *Drosophila melanogaster*, one micropyle is present in a pointed protrusion at the anterior tip of the egg. In the grasshopper *Eyprepocnemis plorans*, an average of 40 micropyles are arranged in a ring-like manner close to the posterior pole. Queens of the termite *Reticulitermes speratus* can produce offspring both sexually and asexually (parthenogenetically) by controlling proportion of micropyleless eggs over time (Yashiro and Matsuura, 2014).

Eggs of many cnidarians including hydras, hydrozoan jellyfish, sea anemones, and corals, generally lack the firm egg coat, and the plasma membrane is covered with jelly layer. Nevertheless, site of sperm adhesion and subsequently site of sperm fusion are restricted to the plasma membrane of the animal pole just above the female pronucleus. In some species such as *Hydra* and *Hydractinia*, site of sperm-egg fusion appears as an indentation called the fertilization pit.

Monospermy and Physiological Polyspermy

In general, the entry of more than two spermatozoa into the egg cytoplasm, referred to as polyspermy, causes aberrant effects on meiosis completion or embryo development and hence embryonic death, due mainly to excess male centrosomes delivered into the egg. Thus, most animals have evolved multiple mechanisms by which monospermic fertilization is ensured (known for polyspermy block).

Changes in the electric potential of the egg plasma membrane are thought to play a central role in the fast block to polyspermy in various animals (Gould and Stephano, 2003). In sea urchin eggs, a resting membrane potential of approximately -70 mV shifts to $+20$ mV within a few seconds after the contact of a fertilizing spermatozoon. When Na^+ concentration is lowered in the surrounding water, this sperm-induced jump-up in the membrane potential, i.e., depolarization, does not occur, resulting in polyspermy. In addition, holding the membrane potential of unfertilized eggs at either $> +5$ or < -20 mV prevents sperm entry, whereas holding them between -20 and $+5$ mV allows repeated sperm entries. Thus, it is thought that the fertilizing spermatozoa can enter the egg within the narrow window of time during which Na^+ -dependent depolarization takes place (or the egg becomes depolarized), ensuring monospermy at the initial phase of fertilization. However, it is a matter of debate whether or not the fast electrical polyspermy block is necessary under physiological conditions where not so many spermatozoa are assumed to reach the egg.

In many other marine invertebrates including ribbon worms, polychaete worms, echiuran worms, starfish, ascidians, bivalves, and gastropods, a similar depolarization from the resting negative potentials (between -80 and -10 mV) to the positive levels (between $+10$ and $+60$ mV) mainly due to Na^+ influx or Na^+ and Ca^{2+} influxes is also thought to play a role in the fast polyspermy block. In contrast, in eggs of the crab *Maja squinado*, fertilization induces K^+ efflux-mediated hyperpolarization (a decline of the membrane potential from -50 to -80 mV), which is accounted for polyspermy block. In eggs of freshwater lamprey and frog, fertilization evokes Cl^- efflux-mediated depolarization, resulting in polyspermy block.

In contrast to the aforementioned animals that show a fast electrical block to polyspermy, comb jellies, jellyfish, insects, teleost fish, newts, reptiles, birds, and mammals are regarded as devoid of such a system. Instead, in most teleost fish and various insects, the number of spermatozoa adhering to the egg in the initial phase of fertilization is limited in space and time by having a single or multiple micropyles on the chorion of an egg. Jellyfish eggs also ensure monospermic fertilization by restricting the site of sperm-egg fusion to the plasma membrane of the animal pole (5–10 μm in diameter).

After the successful entry of a spermatozoon, the fertilized egg generally exhibits a so-called late block to polyspermy, which includes physical and chemical modifications of the egg coat and the egg plasma membrane. In animals such as sea urchins, frogs, and mammals, secretion of the cortical granules results in the release of proteinous (e.g., proteases and ovoperoxidase) and chemical (e.g., H_2O_2) components to modify the egg coat (e.g., formation of the fertilization membrane in sea urchin eggs), which prevents the extra spermatozoa from adhering to or passing through it (Wessel and Wong, 2009). The cortical granule exocytosis in teleost fish eggs causes shrinkage of inner layer chorion, resulting in a decrease in the diameter of micropyle or the complete closure of this gate to abolish the following sperm entry (Murata, 2003). Late block to polyspermy at the level of plasma membrane independent of membrane potential has been reported in many animals including jellyfish, bivalves, and mammals. The loss of Juno (folate receptor 4), an egg receptor for the sperm ligand Izumo, is one of the reasons for the late plasma membrane block in mammalian eggs.

In contrast to monospermic fertilization that is absolutely necessary for eggs of many species to develop normally, there are some animals where polyspermy is mandatory for normal embryo development. This phenomenon, called physiological polyspermy, is found in vertebrates such as elasmobranchs (sharks and rays), urodeles (newts and salamanders), reptiles, and birds, as well as marine invertebrates such as comb jellies. In these animals, only a single sperm nucleus is selected to fuse with the egg nucleus, resulting in formation of a diploid zygotic nucleus. Consequently, other sperm nuclei and accompanying centrosomes are diminished without participating in the formation of fertilized egg (Iwao, 2012). Although monospermic fertilization is more common in insects, polyspermic fertilization is often seen in some species. Similarly, only a single male nucleus can unite with a female nucleus. This pattern is called compensable polyspermy (Snook *et al.*, 2011). Even in the species displaying physiological and compensable polyspermy, the time of fertilization is limited. For instance, fertilized avian eggs quickly lose their fertilizability due to the formation of chalaza-layer immediately after ovulation.

Egg Activation by Ca^{2+} Rise

Fertilized eggs exhibit a series of processes required for the release from cell cycle arrest, by which normal development can start, which is collectively called egg activation. The key event that leads to egg activation is a transient rise in the cytoplasmic Ca^{2+} concentration in fertilized eggs (from 100 nM to 2–3 μM in the case of sea urchins), which in turn modifies the activities of various Ca^{2+} -dependent proteins including protein kinases and phosphatases. Although it is known that eggs of all animal species investigated so far exhibit a Ca^{2+} rise at fertilization, there are considerably greater interspecific variations in the source of Ca^{2+} , the pattern of Ca^{2+} rises, and even the role of elevated Ca^{2+} (Kashir *et al.*, 2013).

In most animals, a fertilizing spermatozoon carries a substance(s) that triggers Ca^{2+} rise in the egg. In ribbon worms, ascidians, newts, birds, and mammals, it is thought that a sperm-borne soluble factor, called sperm factor, that evokes the Ca^{2+} rise is introduced into the egg cytoplasm after sperm-egg fusion. Recent analyses have shown that mammalian sperm factor corresponds to a sperm-specific phospholipase C (PLC) called PLC, which cleaves phosphatidylinositol 4,5-bisphosphate (PIP_2) into IP_3 and diacylglycerol in eggs. In newts, delivery of citrate synthase from spermatozoa is the main pathway to trigger the Ca^{2+} rise probably through elevation of PLC activity in eggs. In contrast to the internally acting soluble sperm factor, several lines of evidence indicate that many other animals including echinurans and frogs use the system where sperm protein binds to an egg receptor that links to intracellular pathways leading to a Ca^{2+} rise. In some animals such as *Drosophila*, prawns, and zebrafish, a Ca^{2+} rise occurs at the time of ovulation without stimulation by spermatozoa. Up-regulation of egg surface mechanosensitive ion channels that occurs in response to squeezing or swelling the egg would be responsible for the Ca^{2+} rise in *Drosophila*. Induction of Ca^{2+} rise without sperm would lead the way that eggs can also reproduce via parthenogenesis, which is frequently seen in arthropods and other animals.

Both external medium that contains Ca^{2+} (such as seawater) and intracellular organelles that store Ca^{2+} (such as the endoplasmic reticulum, ER) are the potential sources from which the Ca^{2+} are mobilized to the egg cytoplasm. Typically, a Ca^{2+} wave starts at the site of sperm-egg fusion and thereafter propagates the antipode (Fig. 2(A)), which is observed at fertilizations of such animals as jellyfish, echinoderms, ascidians, amphibians, and mammals. Polyspermic fertilization in newt eggs is accompanied by multiple Ca^{2+} waves that originate from respective sperm-egg fusion sites. Since each Ca^{2+} wave in newt eggs only propagates to one-eighth to one-quarter of the egg, multiple sperm entries are required to generate a Ca^{2+} rise over the entire egg. The Ca^{2+} waves initiated from a single or multiple points are mainly mediated by ER membrane-located IP_3 receptors that promote the Ca^{2+} release from the ER lumen. In contrast, a centripetal Ca^{2+} wave initiated at the whole cortex (Fig. 2(B)), which is probably dependent on Ca^{2+} influx through voltage-gated Ca^{2+} channels on the plasma membrane, is detected in fertilized eggs of ribbon worms, bivalves, limpets, and echinurans.

In jellyfish, some bivalves, limpets, echinurans, sea urchins, starfish, fish, and frogs, a single Ca^{2+} rise lasts for a few minutes to several tens of minutes (Fig. 2(C)). Fertilized eggs of ribbon worms, some bivalves, polychaetes, ascidians, and mammals, in contrast, exhibit repetitive Ca^{2+} rises, called Ca^{2+} oscillations, that persist for several tens of minutes to several hours (Fig. 2(D)).

In spite of the difference in the pattern and source of Ca^{2+} , one of the universal roles of the Ca^{2+} rise in the entire egg is to trigger the resumption of cell cycle; unfertilized eggs are arrested at either the first prophase (e.g., some bivalves and echinurans), the first metaphase (e.g., some bivalves, limpets, insects, and ascidians), the second metaphase of meiosis (e.g., most vertebrates), or the G_1 stage after completion of meiosis (e.g., jellyfish and sea urchins). It is known that Ca^{2+} -dependent proteins such as Ca^{2+} /calmodulin-dependent protein kinase II and calcineurin are involved in the downstream effector molecules responsible for the resumption of cell cycle in insects, ascidians, frogs, and mammals. A Ca^{2+} rise also modifies the physical and chemical properties of egg coat and plasma membrane through cortical granule exocytosis or other mechanisms to protect embryos as well as to prevent polyspermy in the later

Fig. 2 Spatial and temporal patterns of intracellular Ca^{2+} rise in fertilized eggs. (A): Point-source Ca^{2+} wave initiated at the sperm-egg fusion site. (B): Centripetal Ca^{2+} wave initiated at the whole cortex. (C): Single Ca^{2+} rise. (D): Ca^{2+} oscillations.

phase. Ca^{2+} influx through voltage-dependent Ca^{2+} channels in many marine invertebrates and Cl^- efflux through Ca^{2+} -activated Cl^- channels in frogs contribute to the membrane depolarization that serves as fast electrical polyspermy block. It seems that the formation of cytoplasmic protrusion generated by a local Ca^{2+} rise helps the fertilizing spermatozoa on the vitelline envelope to enter the egg cytoplasm efficiently in some polychaetes, where unfertilized eggs have a wide perivitelline space (Nakano *et al.*, 2008). The pattern and amplitude of Ca^{2+} rise at fertilization also influence the later embryonic development (Whitaker, 2008). In ascidian and frog eggs, the direction of Ca^{2+} wave may specify the orientation of an embryonic axis. In mammals, abnormal patterns of Ca^{2+} oscillations are known to lower the developmental competence of blastocysts, resulting in fewer offspring.

Glossary

Cryptic female choice The processes used by females to bias paternity towards certain males, a type of post-copulatory sexual selection.

Delayed fertilization The separation in time between mating (in particular insemination) and the fertilization of an ovum—used as a male-active and female-active synonym of ‘female sperm storage’.

Delayed ovulation The separation in time between mating and ovulation by a female, often used as a female-active synonym of ‘female sperm storage’ and ‘delayed fertilization’.

Female sperm storage The maintenance of viable sperm by females between insemination and fertilization.

Male sperm storage The maintenance of viable sperm by males between production (spermatogenesis) and use (insemination).

Spermatheca The sperm storage organ found in some invertebrate females.

Sperm competition The processes related to sperm biology including number, concentration, behavior, morphology, and related seminal fluids, that increase a male’s chances of fertilization when females mate with multiple males during a single reproductive bout.

Sperm longevity The duration of time sperm remain viable.

Sperm motility The activity patterns in particular flagellar (or similar) movement of spermatozoa.

Sperm senescence The process of aging in sperm that is associated with a decrease in function.

Sperm viability The ability of sperm to successfully fertilize an ovum.

Sperm Storage

The production of spermatozoa and their subsequent use by males (insemination) or by females (conception) may be separated by extended periods of time ranging from hours to days, months and even decades. Sperm storage is likely ubiquitous in most animals with internal fertilization because sperm are rarely, if ever, deposited directly in contact with the eggs. Both sexes are able to store sperm, and the numerous adaptations required for long-term storage by one sex, may provide pre-adaptations to sperm storage in the other sex, or become arenas of conflict. Here we deal primarily with female long-term sperm storage in mammals, and other vertebrates, though sperm storage is also common in invertebrates.

Sperm storage results in a temporal separation of events between spermatogenesis, mating and conception. Thus, sperm storage may be adaptive in a wide range of habitats, in species with diverse life histories, and it is likely to influence the evolution of mating systems, post-copulatory sexual selection such as cryptic female choice and sperm competition, as well as the degree of sexual conflict (reviewed in [Orr and Brennan, 2015](#)).

Male Sperm Storage

Male sperm storage (MSS) is the maintenance of mature viable spermatozoa for extended periods after spermatogenesis but before ejaculation. Male sperm storage refers to the temporal separation between sperm production and sperm transfer, and therefore MSS is likely found in nearly all animals as males are unlikely to produce sperm at the moment of insemination.

MSS can vary from a few hours or a few days (short-term), to several weeks or months (long-term). Long term MSS likely requires specializations to maintain the vitality of sperm and prevent the natural decline in motility and fertilization ability that is known to occur with aging sperm in many species including humans ([Racey and Entwistle, 2000](#)). These specializations however are poorly known. Long-term MSS is known in mammals primarily from bats where many species produce sperm in the spring or summer and these sperm are stored until their use in the late fall and winter ([Racey and Entwistle, 2000](#)). This phenomenon is also known to occur in some snakes ([Almeida-Santos *et al.*, 2004](#)).

In mammals, sperm are maintained in the epididymis until ejaculation, when contractions during copulation result in sperm transport along with secretions from the male reproductive tract (alkaline sugars and zinc in the prostate, enzymes, sugars, prostaglandins and other substances in the seminiferous vesicles). In other species, sperm may be maintained in the testes and spermatic cords (e.g., sharks), the caudal portion of the vas deferens (e.g., birds), or in spermatophores (e.g., salamanders).

Female Sperm Storage

Female sperm storage (FSS) is the extended maintenance of viable sperm received during mating until their use for conception. Female sperm storage (FSS) has been described in nematodes, annelids, squid, arthropods, and in all major groups of vertebrates including amphibians, cartilaginous fishes (sharks and rays), bony fish, squamates, reptiles birds, and mammals (Fig. 1). Female sperm storage can last from hours (mice) to days (dogs and horses), several years (turtles), and up to decades (leaf-cutter ants) (Suarez and Pacey, 2006; Orr and Zuk, 2013; Orr and Brennan, 2015).

Historically FSS has also been termed ‘delayed fertilization’. However, this term presents females as passive participants in the process of sperm storage by making it seem as if sperm themselves are simply awaiting their opportunity to fertilize an egg. The distinction between passive and active FSS is important, as selection on females to store sperm long-term is often confused with sperm survival inside the female that may result from selection on males to keep their sperm alive, even if prolonged survival of sperm inside the female reproductive tract runs counter to her reproductive interests. The term ‘sperm storage’ as currently implemented by some researchers may be referring to what may simply be ‘sperm longevity’ (sperm surviving inside the female but with no clear ‘female active’ role in storage) (see [Section Glossary](#)).

Similarly the term ‘delayed ovulation’ is used in the literature in place of long-term sperm storage. Delayed ovulation places the emphasis on just one aspect of female physiology that refers to the timing when ovulation takes place relative to insemination. Both delayed fertilization and delayed ovulation highlight only two aspects of the multivariate physiological processes that take place in order for fertilization to occur, and thus we focus on more neutral terminology.

The general lack of refined terminology and consistency of criteria for assigning FSS has been problematic. For example, several studies, have mistakenly described female sperm storage based on births occurring later than was expected (e.g., in skinks; [Sever and Hopkins, 2004](#)); a phenomenon that instead may have been caused by other types of reproductive delays (implantation or development) and not true FSS ([Birkhead and Møller, 1993](#); [Neubaum and Wolfner, 1999](#)). Similarly, several observations once believed to provide evidence of long-term FSS were later discovered to have resulted from parthenogenetic reproduction (‘virgin birth’, i.e., the use of unfertilized eggs to produce offspring) in a few vertebrates (e.g., some lizards, sharks, and snakes – see [Neubaum and Wolfner, 1999](#); [Holt and Lloyd, 2010](#)).

Thus, the need to clarify what constitutes FSS and the criteria to study its causes and consequences is apparent. Below we present criteria that can be used to study FSS in diverse taxa ([Orr and Brennan, 2015](#)), and review examples from major taxonomic groups. In all species, sperm will suffer from senescence and lose their fertilizing ability within some period of time after being made. Therefore, prolonged sperm storage by the female requires some mechanism to keep sperm viable, and often these mechanisms include specialized morphology, physiology, biochemistry and associated changes in sperm behavior.

Criteria Associated With Long-Term Female Sperm Storage

Anatomy

The presence of specialized sperm storage structures is strong evidence of long-term active FSS. Some of these structures are dedicated only to storing sperm (e.g., spermatheca, sperm storage tubules etc.), but others have been co-opted from pre-existing structures (e.g., folds in the lining of the uterus or cervix, the utero-tubule junction, uterine glands, etc.) as the site of sperm maintenance (Fig. 2). Therefore the absence of sperm storage organs per se is not evidence that long-term sperm storage has not evolved. Instead, in the absence of modified sperm storage structures, the location of sperm consistently in pre-existing locations (e.g., uterine glands or the utero-tubule junction), sperm interacting with epithelial cells of the female reproductive tract, for example, by having an ‘organized’ arrangement with sperm heads facing the epithelial lining of the female reproductive tract (e.g., bats, marsupials, dogs, humans), can serve as evidence of sperm storage ([Racey et al., 1987](#); [Suarez and Pacey, 2006](#); [Orr and Brennan, 2015](#)).

Females in some taxa have not only one but several types of sperm storage organs (e.g., both spiders and fruit flies – see examples below). The interpretation of such elaborate morphology for sperm storage in these groups might be interpreted as evidence of refined female cryptic control of sperm (i.e., [Eberhard, 1996](#)).

Additional structures associated with or actual placement inside of sperm storage structures include modified glands usually of secretory natures (e.g., in some marsupials [Kress and Morson, 2007](#)). Such glands may present the female with the capability to nourish sperm while in storage (see [Section Physiology](#)).

Physiology

Sperm maintained within female humans, horses, pigs and dogs all are viable for a longer period of time than in similar conditions outside the female (Suarez and Pacey, 2006) suggesting that additional aspects of female biology may contribute to sperm storage.

Key aspects of female physiology are often also modified to enable long-term FSS. First, immune suppression is common, as a means to prevent the destruction and removal of stored sperm. Such immune suppression is taxon-specific (e.g., low leukocyte counts in mammals and plasmatocytes, crystal cells or lamellocytes in insects). Lowered immunity is a key cost of sperm storage such as in leaf-cutter ants (Baer *et al.*, 2006). However, a depressed immune response likely imposes selection on females to have a localized rather than systemic immune response to keep sperm from being destroyed by her immune system. Therefore the immune suppression that accompanies sperm storage is typically restricted such as in the oviduct of many mammals (Suarez and Pacey, 2006).

Females may also carefully regulate and maintain areas of specific pH and/or temperatures that are conducive to maintaining or even increasing sperm longevity (Holt, 2011; Suarez and Pacey, 2006; Suarez, 2008). Indeed, the pH of areas where sperm may be maintained for extended periods of time, for example, the oviduct in humans has a higher pH than the vagina that is more acidic, and this helps protect sperm in the oviduct (Suarez and Pacey, 2006).

Sperm have to come out of storage if they are to be successfully used for fertilization, and this event should coincide with ovulation. There is an interplay between male and female physiology for these events to coincide. When ovulation occurs, females may trigger release of sperm from storage areas/sites and sperm can become active in preparation for motion towards the site of conception during this period (Holt, 2011; Suarez and Pacey, 2006). Suspected mechanisms for this “re-activation”, i.e., hyperactivation and eventual capacitation to enable fertilization include changes in levels of cytoplasmic calcium (Suarez and Pacey, 2006). Similarly heparin and pH changes may change activity in bull sperm and may play an additional role in this process (Suarez and Pacey, 2006). However in birds, sperm behavior changes before sperm come out from storage. Sperm stop moving and therefore they flow out of the sperm storage tubules (see [Section Sperm storage in birds](#)). Whether this change in sperm behavior is mediated by the female or the male is unknown.

Females may nourish sperm while in storage (see [Sections Sperm storage in fruit flies](#) and [Sperm storage in bats](#)). However, demonstration of sperm nourishing by females remains debated – particularly in vertebrates.

Behavior

Upon ejaculation, sperm are typically propelled by muscular contractions of ejaculation in males, and are not actually swimming. However, when entering the female reproductive tract, sperm often begin to swim using their flagella to reach the female eggs or her sperm storage organs. Sperm movement has been shown to be oriented toward a flow gradient (rheotaxis), but female contractions and movement of cilia in the lining of her reproductive tract can facilitate sperm transport upstream (Suarez and Pacey, 2006).

In addition, sperm orient themselves through both chemical and temperature gradients (chemotaxis and thermotaxis). During storage sperm activity (movement) as mentioned above is usually limited (except in birds and fruit flies, see below). This lack of motion may allow sperm to conserve the limited energy stored in the mitochondria, so that this energy can be used to propel sperm towards the eggs as needed for fertilization.

Why Store Sperm?

Long-term FSS presents females many advantages including greater flexibility in timing of reproduction and in cryptic female choice. For example, females can separate the act of mating from the event of fertilization through FSS (Eberhard, 1996; Birkhead and Møller, 1993). If males and females have limited periods of interaction such as in migrating species – mating during limited periods of mate availability is extremely important – but so too is timing when offspring hatch or are born to coincide with abundant resources. Females thus, are limited by their ability to time mating, and parturition or egg-laying. By storing sperm, a female may be well-prepared to mate when needed (and store sperm) and still carefully time a variety of other reproductive events with advantageous biotic and abiotic conditions such as food availability, precipitation and temperature (see Sandell, 1990; Birkhead and Møller, 1993). Furthermore, females may receive indirect genetic benefits through increased offspring quality from storing sperm from multiple males, and deciding which exact sperm to use for fertilization. For example, some species with large home-ranges may have decreased likelihoods of encountering a mate. In such a system, females may accept sperm from less preferred mates as a form of “bet-hedging” or “fertilization insurance”, but if she finds a superior mate later in the season, she can preferentially use his sperm for fertilization (e.g., Eberhard, 1996).

In addition to allowing females increased opportunity for cryptic choice, long-term FSS raises the opportunity for sperm competition by increasing the likelihood a female may have sperm from multiple mates in her reproductive tract at the same time. Evidence has been found that males in bat species where females store sperm invest more in sperm production (Orr and Zuk, 2013), and thus may incur more sperm competition (Briskie and Montgomerie, 1993). Males then are expected to be under selection to modify their sperm and ejaculates, to bias paternity in their favor under those conditions. In addition to helping males outcompete the sperm of other males, these adaptations can include taking advantage of female resources or manipulating her physiology during storage, leading to sexual conflict.

Examples of Sperm Storage

Sperm storage in fruit flies

Perhaps the best example of sperm storage comes from insects, in particular fruit flies of the genus *Drosophila*. In this model system it has been repeatedly shown that females and males both play key roles in the successful storage of sperm, which from a single mating can last the lifetime of a female (~2 weeks) if sperm are not depleted prior to her death (reviewed in box 1 Orr and Brennan). Several female organs are important for sperm storage including a receptacle that maintains sperm for short-term storage, and paired spermatheca where sperm are stored long term. Female fruit flies have active control of sperm movement and thus, may have the ability to bias the use of sperm (cryptic female choice).

During ovulation sperm are released for fertilization. Genetic underpinnings of the molecular signal for release have clearly demonstrated a female role in this function (Wong *et al.*, 2008). However, male roles are also likely, but less well known. In most aspects of fruit-fly sperm storage both sexes produce key substances necessary for successful female sperm storage (males in the semen and females by associated glands (e.g., spermathecal secretory cells and parovaria)) (Wong *et al.*, 2008; reviewed Orr and Brennan, 2015). Genetic mutants and knockouts for these substances are no-longer able to store sperm. Sperm storage no-longer functions properly if the female and/or male production of relevant proteins is curtailed. Thus, at least in this one well-studied example we can see clear evidence of co-evolution between the sexes.

Sperm storage in birds

All birds examined to date have specialized female sperm storage organs (Fig. 2). Female turkeys may lay fertilized eggs 71 days after their last copulation, but shorter durations of sperm storage are more typical (Briskie and Montgomerie, 1993; Blesbois and Brillard, 2007). As in many other taxa, sperm are subjected to intense selection in the vaginal environment before being moved to storage, and to ‘survive’ this process the male relies at least partly on immunoglobulins found in his sperm flagella (Blesbois and Brillard, 2007).

Specialized sperm storage tubules (SSTs) are cylindrical blind-ended sacs that can house several sperm each. These sacs are found in the internal mucosa of the uterovaginal junction, and the lower portion of the infundibulum, closer to the fertilization site (Briskie and Montgomerie, 1993). Their number varies across species between 2000 in passerines and 20,000 in the Turkey.

Unlike sperm in many other taxa that remain immotile while stored, avian sperm are likely moving in the SSTs, and it is possible that exit from the tubules occurs when sperm stop moving and retrograde female-driven flow pulls them out of the tubule (Blesbois and Brillard, 2007). When females ovulate, the last sperm to enter these tubules can exit for conception to occur and thus sperm storage in birds leads to ‘last male advantage’. There is no evidence that females can selectively utilize sperm from particular males once sperm are in storage.

Not only do female birds have specialized anatomy for sperm storage, but their physiology also supports long-term sperm storage. It is possible that lipid components of the cells that make up the SSTs provide some nourishment to the sperm. The

prevention of oxidative damage to sperm during storage is likely achieved by polyunsaturated fatty acids present in the sperm membrane itself, and enzymes from the SST cells (Blesbois and Brillard, 2007).

Sperm storage in bats

Among mammals the longest periods of sperm storage are known from bats (Chiroptera). Female bats of some species can store sperm for upwards of a year (~300 days) (little brown bats, *Myotis lucifugus*, Racey *et al.*, 1987). Perhaps surprisingly, unlike many other species with long-term female sperm storage, bats do not usually have modified organs or structures, and instead use pre-existing structures such as folds in the lining of the uterus or the utero-tubal junction to store sperm (Fig. 2).

Several aspects of bat biology may explain the long duration of FSS. Males of most (if not all) temperate species undergo spermatogenesis in the spring/summer, and then store sperm (MSS) until copulation takes place in the fall/winter. Thus, modifications to spermatozoa for male sperm storage (anatomical, physiological or otherwise) may pre-adapt sperm for long-term female sperm storage (see Section Male Sperm Storage, Orr and Brennan, 2015). Furthermore, thermal biology (hibernation) may be a key aspect of sperm storage (Racey *et al.*, 1987; Orr and Zuk, 2013). Female bats of many sperm-storing species (particularly temperate ones) usually mate in the fall and store sperm throughout the winter when their core body temperature is extremely low (approximating ambient, i.e., while hibernating). This low body temperature may facilitate the maintenance of sperm by subsequently lowering the metabolic rate and thereby reducing possible oxidative damage. Although most sperm storing species are indeed found in temperate regions where females hibernate, a few tropical species also have long-term FSS, so hibernation is not a complete explanation for long-term sperm storage in bats.

Sperm storage in humans

Suarez and Pacey (2006) summarized what is known about potential sperm storage in humans, and we present the most relevant details here. After ejaculation, sperm are deposited in the anterior part of the vagina, and form a loose gel that may help keep sperm near the cervical entrance. Most sperm are lost as backflow and only a small fraction of the ejaculate (1%) ends up in the uterus. Changes in the hydration of the cervical mucus allow sperm to pass the cervix more easily, and there may be cervical crypts that could either entrap or store sperm. Sperm have been found still motile in the cervix up to 9 days after copulation. However, such observations may be due to sperm coming back down from the uterus, rather than actually stored in the cervix. Furthermore, it is unknown whether these sperm maintain any fertilizing potential. These could be argued to be only cases of sperm 'survival', i.e., male-driven sperm viability without an active female role in maintenance. In addition to the crypts, another potential site for sperm storage in humans may be the lining of the oviducts. In vitro experiments have shown that only healthy sperm are found attached to this lining, while abnormal sperm are found elsewhere (Ellington *et al.*, 1998). However, just as the case with 'storage' in cervical crypts, this could be evidence of sperm survival, rather than sperm storage. Therefore, evidence that humans have specialized sperm storage sites is lacking.

Nevertheless, human sperm seem to be protected against immune responses and phagocytosis, as the immune cells present in the female vagina and cervix preferentially attack potential microbes rather than sperm. Seminal plasma that coats spermatozoa also may protect them against leukocyte attack, but eventually all leftover sperm will be eliminated by the immune system. Sperm may also derive a benefit by attaching to the oviduct lining, as attached sperm survive longer than unattached, and female secretions may mediate this increased survival.

Abbreviations

ACTH	Adrenocorticotropin hormone
AH	Adenohypophysis
dio2	Type II iodothyronine deiodinase
FS	Folliculostellate cells (FS)
FSH	Follicle-stimulating hormone
GABA	Gamma-aminobutyric acid
GFAP	Glial fibrillary acid protein
GFP	Green fluorescent protein
GH	Growth hormone
GnIH	Gonadotrophin-inhibiting hormone
GnRH	Gonadotropin-releasing hormone
LH	Luteinizing hormone
MSH	Melanocyte-stimulating hormone
NH	Neurohypophysis
NPY	Neuropeptide Y
PPD	Proximal pars distalis
PI	Pars intermedia
POMC	Proopiomelanocortin
PRL	Prolactin
PT	Pars tuberalis
RPD	Rostral pars distalis
T3	Triiodothyronine
TSH	Thyroid-stimulating hormone
SL	Somatolactin

The pituitary gland, also named the hypophysis, is a major endocrine gland located just below the hypothalamus to which it is attached by the pituitary stalk. It is present in all vertebrates and has an overall conserved organization and functions despite the fact that some significant variations can be observed between the different groups of vertebrates.

General Organization of the Pituitary in Tetrapods

In all vertebrates, the pituitary (also called hypophysis) consists of two parts, the adenohypophysis and the neurohypophysis. The adenohypophysis contains the different cells secreting the classical pituitary hormones and thus represents the glandular part of the pituitary. The neurohypophysis consists in an accumulation of neurosecretory fibers originating from different part of the brain and secreting various peptides in the vicinity of the pituitary cells (in fish only) or into the blood stream. In mammals (and other land vertebrates), the pituitary is often divided into three lobes (see Fig. 1): the anterior, intermediate and posterior lobes.

The Anterior Lobe

The anterior lobe contains the corticotrophs (ACTH cells), the mammatrophs (prolactin cells, PRL cells), the somatotrophs (growth hormone cells, GH cells), the thyrotrophs (TSH cells) and the gonadotrophs (LH/FSH cells). In tetrapods, the anterior lobe does not

Fig. 1 The pituitary nomenclature is somewhat confusing. This figure shows the different synonyms for the different regions in land vertebrates and teleost fish.

receive a direct innervation due to the existence of a hypothalamo-pituitary portal system whose primary plexus of capillaries is located in the external zone of the median eminence. The median eminence is located in the floor of the hypothalamus and, at this level, the neurohormones secreted by the hypophysiotropic neurons are liberated in the vicinity of blood vessels and reach the anterior lobe via the blood stream to act on their target cells (Fig. 2).

The Intermediate Lobe

Between the anterior and nervous lobes is found the intermediate lobe (pars intermedia) which, except in fish, contains only one cell type, the melanotrophs (MSH cells). These cells secrete neuropeptides processed from the proopiomelanocortin gene. However, in contrast to the ACTH cells of the anterior lobe, ACTH is further processed through alternative splicing into α -MSH and CLIP. Beta-lipotrophin is further cut into γ -LPH, β -MSH and β -endorphin. The development of the pars intermedia varies considerably from species to species. While it is very well developed in teleost fish, it must be emphasized that in birds, the pars intermedia is lacking. In contrast to the anterior lobe, the pars intermedia receives a direct innervation from the hypothalamus. For example, in mammals, amphibians and teleosts, GABA, NPY and dopamine fibers have been reported (de Rijk *et al.*, 1990). In teleosts, the intermediate lobe harbours a cell type that is unique to fish, that produces a hormone belonging to the growth hormone/prolactin family, somatolactin.

Fig. 2 Transcription factors implicated in the development of the anterior pituitary. Adapted from Cohen, L.E., Radovick, S., 2003. Molecular basis of combined pituitary hormone deficiencies. *Endocr. Rev.* 23 (4), pp. 431–442.

The Posterior Lobe

The posterior lobe (also called neural lobe) corresponds to the neurohypophysis and consists in an accumulation of nerve terminals which secrete various peptides, mainly arginine-vasopressin and oxytocin in mammals (related peptides in other vertebrates), directly into the blood stream. These nerve endings originate from the paraventricular and the supraoptic nuclei in mammals and from the magnocellular preoptic nucleus in teleost fishes.

The Pars Tuberalis

The pars tuberalis (PT) is located between the median eminence and the anterior lobe. It is well-developed in mammals where it contains both thyrotrophs and folliculostellate cells (see below). Although the function of the PT remained unknown for a long time, the PT recently surfaced as a major player in the regulation of seasonal reproduction. Surprisingly, cells in the PT express the highest density of melatonin receptor in mammals and birds and recent data have led to the assumption that the PT-specific thyrotroph feedbacks on the median eminence area to modulate DIO2 activity. In turn, T3 acts on GnIH and kisspeptin neurons to modulate GnRH release (review [Wood and Loudon, 2017](#)).

In lacertilian reptiles, it was shown that the PT develops from the Rathke's pouch, as it is the case of mammals, but during development cells of the PT gets progressively separated from the pars distalis and become completely incorporated to the lateral hypothalamus ([Bello et al., 1991](#)). In teleost fishes, there is no anatomically-distinct PT, but some studies have suggested that the saccus vasculosus (SV) would play in fish the role of the PT in mammals. The rationale for this assumption is that the coronet cells of the SV express, TSH β and DIO2 mRNAs in masu salmon. While this assumption may be true in some seasonal species like the salmon, it is unsure how this can be extended to all teleosts given that many seasonal fish do not exhibit such a structure (see below). Furthermore, studies in the rainbow trout failed to detect melatonin receptors in the SV.

The Folliculostellate Cells: The 7th Cell Type of the Anterior Lobe

In addition to the 6 classical secretory cell types, the anterior lobe also harbours the so-called folliculostellate cells (FS). These cells have a typical star-shape with long processes anchored by a basement membrane, hence their name ([Inoue et al., 1999](#)). FS do not contain secretory granules and they have been shown to release a number of cytokines and growth factors that participate in the regulation of anterior pituitary cell activity. FS cells are linked to each other by means of gap junction and form a meshwork that surrounds lobules containing secretory cells. It has been reported that FS cells provide large-scale communication system that allows rapid transfer of information between secretory cells by means of calcium waves that propagate through gap junctions ([Fauquier et al., 2001](#)). Such peculiarities seem to have been conserved invertebrates as it was shown in fishes that FS cells also form a network enabling communication from cell to cell ([Golan et al., 2016](#)).

FS cells express protein S100B, GFAP and vimentin and exhibit characteristics resembling astrocytes. Furthermore, recent data suggest that FS cells could act as stem cells within the pituitary. Recent results using S100B-GFP mice have shown that astrocytes and FS cells share the same differentiation capacity and are both capable to differentiate into skeletal muscle cells ([Osuna et al., 2012](#)). Interestingly, results obtained in rainbow trout, Japanese eel and zebrafish indicate that FS cells express the *cyp19a1b* gene that in the fish encodes the brain form of aromatase. In the eel, it was further demonstrated that SF cells can proliferate and may indeed behave as radial glial cells, which in teleost fishes carry many functions of astrocytes and are considered as neuronal stem cells ([Jeng et al., 2012](#)).

Altogether these results suggest that folliculostellate cells and astrocytes share a common origin and may represent stem cells in the pituitary and the brain, respectively.

Ontogeny of the Pituitary Gland

It is now clear that the origin of the pituitary gland is completely ectodermal. The anterior pituitary develops from an invagination of the roof of the stomodeum known as the Rathke's pouch, while the neurohypophysis originates from the infundibulum which consists of the floor of the hypothalamus. These two tissues come in contact with each other and it is admitted that interactions between the two are essential for the complete development of the gland. Cells in anterior part of the embryonic adenohypophysis proliferate more actively than cells of the posterior part, which causes the formation of two different regions, the future pars distalis, and the pars intermedia. The ontogeny of the pituitary has not been extensively studied in non-mammalian vertebrates but there is no reason to assume that the main mechanisms are different.

A number of homeodomain transcription factors are essential for defining the fate of pituitary lineage ([Fig. 2](#)). Among these factors, *Rpx* and *Pitx1* are present in the developing pituitary and in the adult somatotrophs, thyrotrophs and lactotrophs ([Fig. 2](#)). ACTH and LH/FSH cells develop from independent lineages under the influence of *NeuroD* and *Tpit* or *SF1* and *GATA2*, respectively ([Cohen and Radovick, 2002](#)).

The development of the PT differs from that of the pars distalis. It involves the bHLH transcription factor hairy enhancer of split (*HES1*).

The Pituitary is a Vertebrate Evolutive Novelty

It is usually accepted that the pituitary is a vertebrate evolutionary novelty. Indeed, there is no such homologous organ in invertebrates and although some groups have intended to identify the equivalent of the pituitary in urochordates, the sister group of vertebrates, no one has produced strong evidence for the existence of such an organ. Nevertheless, recent research suggests that cephalochordates may have a structure resembling the Rathke's pouch that expresses neuropeptides and possibly pituitary hormones (Li *et al.*, 2017). In fact, the anterior pituitary gland is supposed to be derived from the adenohypophyseal placode who could potentially have an equivalent in the cephalochordate. In this regard, it is important to keep in mind that the pituitary is derived from the adenohypophyseal neurogenic placode. Such placodes are regions of thickening of the embryonic head ectoderm layer that gives rise to neurons. It is usually considered that neurogenic placodes are found only in vertebrates.

Some authors have suggested that because of the genome duplications, early vertebrates have developed a number of new functions thanks to numerous extra genes and thus exhibit more complexity. At the same time, there is also an increase in size. Hence, while most of the physiological functions remain under the control of the brain, there has been a need for an amplification system that would allow a small number of neurons to control major physiological functions requiring fine-tuning. Thus, the hypophysis appears as a good manner to amplify neural signals in vertebrates in a way similar to the optic gland of cephalopods that also appears as an intermediate gland between the brain and peripheral organs, in particular the gonads.

Hence, in view of this information, it appears that the hagfish pituitary would represent the most ancient form of a "true" hypophysis.

The Pituitary of the Hagfish and Lampreys

Together with lampreys, hagfish (Mixini) represent jawless fish, the sister group of vertebrates. They have a skull but no vertebrate column and they are believed to be the first animals with a well-differentiated pituitary. Hagfish have been shown to have a hypothalamo-pituitary axis. The adenohypophysis takes the form of clusters of cells surrounded by connective tissue. The neurohypophysis is an evagination of nervous tissue that is located dorsal to the adenohypophysis with which it has no connection. Both adenohypophysis and neurohypophysis are wrapped in connective tissues. Hagfish have been shown to have GnRH system and possible three pituitary hormones, gonadotrophs, ACTH and GH (Nozaki, 2013). Recent data in the lamprey have highlighted the existence of two heterodimeric pituitary glycoprotein hormones, lamprey glycoprotein hormone (IGpH) and thyrostimulin. The corresponding receptors have also been characterized (Sower, 2017).

The Pituitary of Chondrosteans

The hypophysis of sturgeons, is flat and elongated in the rostral-caudal direction. It is composed of the adenohypophysis situated rostrally and the neurohypophysis located caudally in close vicinity to the transition zone between the infundibulum and a well developed saccus vasculosus (see below).

A comprehensive description of the hypothalamo-hypophyseal system was reported in the classical studies of Russian researchers. The adenohypophysis consists in a pars distalis and a pars intermedia, and the neurohypophysis is incorporated in a neurointermediate lobe that is made of tubular processes of the bottom of the infundibular wall that penetrate deeply between the cell cords of the pars intermedia. The distribution of the pituitary endocrine cells was studied by immunocytochemical techniques in the adenohypophysis of different sturgeon species and seven types of endocrine cells were identified: the adrenocorticotrophic, prolactin, growth hormone, gonadotrophic and thyroid stimulating hormone cells in the pars distalis, and, similar to teleosts, the melanocyte stimulating hormone and somatolactin cells in the pars intermedia.

In chondrosteans, such as the sturgeons, the hypothalamic floor located dorsal to the pars distalis of the adenohypophysis, resembles a typical median eminence named proximal neurosecretory contact region (Polenov and Garlov, 1973). In this region and the pars distalis there are blood vessels that form part of a hypothalamic-hypophyseal portal system where numerous neurosecretory fibers form synaptic like contacts, and, appear to release neurohormones into the portal circulation. For example, it has been shown that GnRH neurons located in the telencephalon and the preoptic region send projections to the area separating the hypothalamus from the pituitary but they do not enter into the pars distalis. The sturgeon pituitary exhibits the different subtypes found in other vertebrates and the organization of several neuroendocrine systems have been reported in details (Adrio-Fondevila and Kah, *in press*).

The Pituitary of Teleost Fishes

The pituitary of teleosts has been extensively studied in many species due to the fact that this group of fish includes close to 30,000 species and also because interest for commercial species varies from one region to another. Because the evolutive history of teleosts spans about 280 million years, there are significant variations in the organization of the pituitary gland.

Fig. 3 Comparative organization of the hypothalamo-pituitary connections in teleost fishes (A) and mammals (B). In fish, unlike tetrapods, hypothysiotropic neurons send their projections directly into the anterior lobe. Nerve endings may connect directly with secretory cells of the anterior lobe (n1) or establish synaptic like contacts at a basal membrane (n2) that separates the neurohypophysis (NH) from the adenohypophysis. This innervation is homologous to that of the median eminence in tetrapods. In fish and mammals, hypothalamic neurons (ocytocin/isotocin and arginine vasopressin/vasotocin) send their projections to the neural lobe (NH) that in teleosts is intermingled with the pars intermedia forming the neurointermediate lobe. Adapted from Kah, O., Dufour, S., 2011. Conserved and divergent features of reproductive neuroendocrinology in fish. In: Norris, D.O., Lopez, K.H., (Eds.), *Hormones and Reproduction of Vertebrates*, vol. 1: Fishes, San Diego, CA: Elsevier, pp. 15–42.

The Anterior Lobe in Teleost Fish

The anterior lobe of the teleost pituitary exhibits some striking features compared to that of land vertebrates. First, the cells corresponding to a given cell type are often found together in a specific part of the pars distalis. For this reason, the pars distalis is often divided into rostral region, rostral pars distalis, and a proximal region, the proximal pars distalis (Fig. 3). In general, the rostral pars distalis encompasses the ACTH cells and the prolactin cells which in some species, such as the eel of the salmonids, can be organized in follicles. In teleost fish, prolactin is a hormone dedicated mainly to osmoregulation. Prolactin cells exhibit considerable changes in synthesis and secretory activity depending on the similarity of the water. In most cases, ACTH cells are adjacent to the neurohypophyseal digitations that deeply penetrate the anterior lobe. The proximal pars distalis includes the growth hormone secreting cells and the gonadotrophs. In contrast to mammals in which there is a single type of gonadotroph that secretes both LH and FSH, the two gonadotrophins are clearly secreted by different cells in the teleosts (Nozaki *et al.*, 1990). FSH and LH cells differ in their aspect and localization according to the sex cycle. In many species, the LH cells invaded the pars intermedia or the rostral par distalis when the fish reach maturity. Similar to other vertebrates, FSH is involved in follicle growth and LH in ovulation.

The location of the pars intermedia of teleost varies from species to species. In eels, salmonids and most perciforms, the pars intermedia occupies the caudal portion of the pituitary gland, where as in cyprinids the pars intermedia is located ventral to the pars distalis. In all cases, the pars intermedia is deeply invaded by the nervous tissue corresponding to the nervous lobe of tetrapods. For this reason, this part of the gland is often referred to as the neurointermediate lobe (Fig. 1).

Another feature of the pars intermedia of teleost is the unique presence of cells that secrete hormone belonging to the prolactin growth hormone family. This hormone discovered in the flounder by Hirose Kawauchi in 1990, it has an unclear physiological functions that may vary from species to species. It has been involved in skin pigmentation, calcium regulation and/or reproductive functions.

The Pituitary Innervation in Teleost Fish

A major feature of the pituitary of teleost is the existence of a direct innervation of the anterior lobe. In all species, the neurohypophysis penetrates deeply into pars distalis from whose it is separated by a so-called double basement membrane. In many species, there is no direct contact between the neurosecretory fibers and secretory cells of the anterior lobe (Fig. 3). However, detailed studies have reported synaptic-like contacts exhibiting membrane thickening and accumulation of dense clear vesicles directly between nerve endings and secretory cells of the pars distalis. Such nerve endings were characterized and shown to contain dopamine, GABA, neuropeptide Y, GnRH, neurotensin, galanin, somatostatin and other neurohormones that act on the activity of the secretory cells. In species that do not exhibit direct contact between nerve endings and secretory cells, electron microscopy studies have indicated potential release of neurosecretory material close to the basement, which is in continuity with the intracellular spaces. Recently, it has been suggested in zebrafish that GnRH3 terminals could release their products in the vicinity of the gonadotrophs or in blood

vessels. However, in view of the lack of electron microscopy evidence to support these views, this hypothesis should be regarded with caution. In parallel with the rich direct innervation of the anterior lobe a major difference between teleosts and tetrapods is that the fish pituitary carries a plethora of receptors for different neuropeptides. For example, in the case of LH cells in fish, about 20 different factors have been reported to modulate LH secretion *in vitro*. This leads to redundancy and/or compensation and may explain why knocking out the GnRH or the kiss genes do not cause sterility in zebrafish.

The Saccus Vasculosus of Teleosts

Another unique feature of the pituitary teleost is the presence of a circumventricular organ referred to as the saccus vasculosus which is present in some but not all species of teleosts. For example, all salmonids exhibit a well-developed saccus vasculosus, the goldfish or the perciforms do not possess such a structure. Interestingly in the rainbow trout, the coronet cells of the SV exhibit strong immunoreactivity for aromatase B, the product of the *cyp19a1b* gene (Menuet *et al.*, 2003). As already mentioned above, it is believed that the saccus vasculosus is an integrator of photoperiodic cues in at least some teleosts.

Conclusions

In all vertebrates, the pituitary gland is a master gland, which under the control of the hypothalamus orchestrates the main physiological functions. Its overall organization is well conserved indicating that common ancestors to fish and land vertebrates already shared similar organization. The hagfish and lamprey pituitaries may provide an idea of what an ancestral pituitary looked like. Most pituitary hormones have conserved functions, with the exception of prolactin that is believed to serve more than 300 different functions in vertebrates. Prolactin provides a good example of how different animals make use of an existing gene to serve a variety of functions.

Endocrine Control of Reproduction, Fish

Introduction

Fish comprise more than 40% of all vertebrate species and are extremely diverse. Nevertheless, the general endocrine components and pathways that regulate fish reproduction are highly conserved and as in other vertebrates, they are generated by the hypothalamus-pituitary-gonadal (HPG) axis (Levavi-Sivan *et al.*, 2010; Zohar *et al.*, 2010). Sensory information from the internal and external environments as well as social cues (such as presence of a potential mate, temperature, photoperiod, metabolism, energy stores, gonadal state etc.), are processed by the fish brain and integrated by the hypothalamus to initiate and regulate reproductive activity. The hypothalamus reacts to environmental and physiological conditions by synthesizing and releasing neuropeptides (primarily gonadotropin-releasing hormone; GnRH) and monoamines (mainly dopamine) which regulate the activity of endocrine cells in the anterior pituitary. That region of the pituitary produces the gonadotropins follicle stimulating hormone (FSH) and luteinizing hormone (LH). Upon stimulation, gonadotrope cells located in the anterior pituitary produce and release their hormones into the blood (Levavi-Sivan *et al.*, 2010). Both gonadotropins reach the gonads, where they stimulate the synthesis of steroidal hormones that, in turn, regulate maturation of gametes, as well as convey feedback to the hypothalamus and pituitary.

In spite of the diversity of reproductive strategies among the approximately 29,000 recognized fish species, fish share several distinct endocrine characteristics: (i) The fish neurohypophysis is positioned dorsally to the adenohypophysis, in contrast to the anterior-posterior organization of the mammalian pituitary. Moreover, unlike the mammalian adenohypophysis, the teleostean adenohypophysis does not contain a cleft (a remnant of the mammalian Rathke's pouch), and so there is no clear morphological separation into a pars distalis and a pars intermedia as in mammals (Pogoda and Hammerschmidt, 2007); (ii) Fish lack both median eminence and a hypophyseal portal system. Instead, both neurohypophysis and adenohypophysis are directly innervated by hypothalamic nerve terminals (Ball, 1981) and apply a dual mode of gonadotrope regulation by GnRH, combining both neuroglandular and neurovascular components (Golan *et al.*, 2015); (iii) Cells producing distinct gonadotropin are well defined, spatially arranged, and grouped together in particular regions of the gland. In addition, while a single mammalian gonadotrope may produce both FSH and LH, fish gonadotropins are produced and secreted by distinct cell types (Levavi-Sivan *et al.*, 2010). LH cells exhibit close cell-to-cell contacts and form a continuous network throughout the gland while FSH cells are more loosely distributed, still maintaining some degree of cell-to-cell contact by cytoplasmic processes (Golan *et al.*, 2015); (iv) Due to events of whole-genome duplications that have occurred during fish evolution, as many as three GnRH-ligand and five GnRH-receptor (GnRH-R) genes have been identified in certain fish species. By contrast, only one or two such variants occur in mammals. The gene duplication in GnRH ligands has led to segregation in the expression pattern and central function of each ligand. A species-specific variant (seabream-type GnRH; GnRH1) that occurs in fish, is mainly located in the preoptic area, and plays a central role in regulating reproduction. A highly preserved variant (chicken-type cGnRH-II; GnRH2) in the midbrain may act as a neurotransmitter and/or neuromodulator. A salmon-type GnRH (sGnRH; GnRH3) that has been primarily identified in the terminal nerve ganglion and olfactory bulbs, is reported to have a neuromodulatory function (Zohar *et al.*, 2010). GnRH receptors are G-protein coupled receptors (GPCR). Piscine GnRH-Rs lack their C-terminal tail; therefore, no GnRH desensitization exists (Levavi-Sivan *et al.*, 2010).

Owing to their commercial value, the reproductive biology of the various fish species has been well studied. Thus, interest constantly increases in fish as model organisms for basic science, as well as for the agricultural aspects.

Reproductive Strategies

The high variability of fish and the ecological niches they inhabit has led to the adoption of various reproductive strategies including viviparity (*Poecilia*), sequential hermaphroditism (the protandrous seabream or the protogenous orange spotted grouper) and even simultaneous hermaphroditism (Black hamlet). Nevertheless, most fish species are gonochoristic and oviparous, meaning that the sexes are separate and fertilization and embryonal development are external (Yaron *et al.*, 2003). Fish may have synchronous ovaries and spawn only once in a season (carp) or even once in their lifetime (river eel and Atlantic salmon); or they can possess asynchronous (or group-synchronous) ovaries, producing several spawning events during the breeding season. During this period, their ovaries contain several generations of oocytes at various developmental stages. Spawning cycles of asynchronous fish may vary from 24 h in the gilthead seabream, up to one month in tilapia, (Yaron *et al.*, 2003).

Fish with synchronous ovaries undergo sharp metabolic changes during the vitellogenic period that differ from those occurring during final oocyte maturation and spawning. Endocrine changes that support each step reflect relatively simple and well-timed hormonal patterns. In contrast, simultaneous production and maintenance of several oocyte generations in asynchronous ovaries makes the sequential hormone release more complex. These endocrine differences are discussed in the following sections.

The Hypothalamus-Pituitary-Gonadal (HPG) Axis

The HPG axis consists of three major sites of endocrine regulation. A plethora of neuropeptides are secreted from specific neurons in the brain (primarily but not only in the hypothalamus) and form an interface between the central nervous system and the endocrine system. These neuropeptides may directly affect the gonadotropes in the pituitary, or may exert their action via the GnRH neurons. This action stimulates the production and release of two distinct but chemically related gonadotropins: FSH and LH. FSH and LH are released into the circulation, and stimulate the gonads to secrete sex-specific steroids that are responsible for gametogenesis, vitellogenesis and final oocyte maturation in females, as well as spermatogenesis and spermiogenesis in males (Fig. 1).

The Hypothalamus and its Neurohormones

The plethora of neuropeptides and monoamines released by the brain were shown to regulate piscine reproductive functions. These include: GnRH, pituitary adenylate cyclase-activating peptide (PACAP), kisspeptins, Neurokinin B (NKB), Neurokinin F (NKF), Neuropeptide Y (NPY), ghrelin, secretoneurin, leptin, gonadotropin-inhibitory hormone (GnIH), dopamine, serotonin, γ -aminobutyric acid (GABA), spexin, dynorphin, and more.

GnRH was first isolated from mammals, and later from other vertebrates (Sherwood *et al.*, 1983). To date, 30 structurally different forms of GnRH have been identified, while 12 structural variants of the GnRH molecule have been found in different fish species. The N-terminal amino acid sequence (pGlu-His-Trp-Ser) and carboxyl terminal amino acid sequence (Pro-Gly-NH₂) have been conserved over 400 million years of chordate evolution (Kochman, 2012). As indicated by its name, chicken GnRH II (GnRH-2) was first isolated from chicken brain and found to be the most ubiquitous form of GnRH molecule. The brain of most teleosts contains three forms of GnRH, encoded by three distinct genes and differ in their developmental origin, spatial distribution, and function. GnRH1 neurons are hypophysiotropic and are positioned in the preoptic area (POA); GnRH2 neurons reside in the midbrain tegmentum, and are suggested to be involved in food intake and reproductive behavior; and the GnRH3 neuronal population is localized in the terminal nerve and has no direct innervation to the pituitary (Zohar *et al.*, 2010). Some teleost species have only two GnRH forms: the salmon and zebrafish genomes do not contain the GnRH1 form, while catfish and eel lack the GnRH3. The lack of these forms is compensated by the axonal projections of the remaining forms (Abe and Oka, 2011). For example, in zebrafish, some of the GnRH3 neurons developing in the terminal nerve migrate into the hypothalamic POA and innervate the pituitary, suggesting that they acquire the role GnRH1 fulfills in “three-form” fish (Zohar *et al.*, 2010).

As in mammals, GnRH1 neurons in the fish POA display irregular and episodic spontaneous electrical activity with circadian fluctuations in the episodic firing frequency. These irregular activities are in contrast to those of the non-hypothalamic populations

Fig. 1 Schematic diagram displaying HPG axis in fish. Schematic diagram showing potential regulatory signals conveyed by hypothalamic neurons to pituitary cells, leading to the gonads (HPG axis).

of GnRH neurons, i.e., GnRH2 and GnRH3, which display regular pacemaker activities, further supporting their functions other than – hypophysiotropic (Oka, 2010). In contrast to the similarities in the GnRH neurons' electrical activity between fish and mammals, a striking difference can be seen in the structure and function of the GnRH-R. In mammals, constant delivery of high GnRH doses leads to hypoactivity of the gonad and disrupted estrous cycles, due to desensitization of the GnRH-R. In contrast, chronic administration of high doses of GnRH in fish leads to increased gonadotropin release and even to spawning. (Zohar *et al.*, 2010).

While hypothalamic GnRH is a positive regulator of the HPG axis, neuroendocrine release of hypothalamic dopamine serves as a negative effector of HPG activity in many, albeit not all, fish species. Dopamine is a neurotransmitter, synthesized from tyrosine by tyrosine hydroxylase (the rate-limiting enzyme) and Dopa-decarboxylase. Although dopamine is known to have pleiotropic effects on both brain and pituitary functions, its involvement in the endocrine regulation of fish reproduction has been demonstrated in several fish species, including goldfish, zebrafish, carp, African catfish, tilapia, eel, grey mullet, sturgeon, and rainbow trout [reviewed by Levavi-Sivan *et al.* (2010); Zohar *et al.* (2010)]. Contrasting these effects, dopaminergic inhibition was not observed in several marine species, suggesting that its involvement in reproductive function is mainly important in freshwater fish. Dopamine receptors are GPCRs and are classically divided into two principal subtypes, according to their ability to activate (D1-like subtype) or inhibit (D2-like subtype) adenylyl cyclase, the key enzyme in the conversion of adenosine triphosphate to 3'5'-cyclic AMP. Various agonists and antagonists with high specificity to D1 or D2 receptors were employed to demonstrate that the inhibitory effects of dopamine on fish reproduction is due to specific activation of D2-like receptors. Fontaine and colleagues have demonstrated the expression of three D2-like receptors in LH cells in the adenohipophysis of the female zebrafish, and that the dopaminergic innervation of the adenohipophysis originates from the hypothalamic POA (Fontaine *et al.*, 2015). These findings provide neuroanatomical support for the existence of dopaminergic inhibition in piscine reproduction.

During recent years, a large surfeit of novel neuropeptides have been found to regulate the secretion of GnRH in mammals and other non-mammalian vertebrates. However, it was the identification of kisspeptin as an upstream regulator of the hypophysiotropic GnRH neurons that led to a significant change in the way that endocrinologists perceive neuroendocrine regulation of the HPG axis (Tena-Sempere *et al.*, 2012). The discovery that GnRH neurons have Kiss1-receptors (a.k.a. GPR54) was the first indication that the kisspeptin system is involved in the control of fish reproduction (Parhar *et al.*, 2004). Unlike most mammals, which possess only one kisspeptin system (KISS1), the majority of teleosts have two kisspeptin systems, comprised of Kiss1 and Kiss2; and two cognate receptors, Kiss1r and Kiss2r (Biran *et al.*, 2008). Nevertheless, certain fish species have only one kisspeptin gene and two Kiss1R genes; in others, two kisspeptin genes were identified with only one Kiss1R gene. This inconsistency can be explained by the fact that bony fish underwent two complete genome duplications during evolution, and many of these duplicated genes were subsequently lost (Mechaly *et al.*, 2013). As in the case of GnRH, chronic administration of kisspeptin was found to suppress reproductive activity in rats and monkeys (Seminara *et al.*, 2006; Thompson *et al.*, 2006), while chronic administration of kisspeptin in fish leads to increased reproductive functions (Nocillado *et al.*, 2013).

Deletion and site-directed mutagenesis of an estrogen-responsive element (ERE) from the kiss promoters of the protogynous orange-spotted grouper (*Epinephelus coioides*), indicated that Kiss1 is regulated by estradiol 17 β (E2), via the classical pathway utilized by Er β 1, as well as via an activator protein 1 (Ap1)-dependent, non-classical pathway utilized by Er β 2. Kiss2 was also regulated by E2 through the Creb transcription factor, as well as by Er β 1 and Er β 2 pathways. The effects of gonadal steroids on kisspeptin *in vivo* were also demonstrated. In the medaka, Kiss1 neurons drastically change their firing activity according to E2 levels, and in the European sea bass expression levels of Kiss2 were affected by circulating testosterone levels (Alvarado *et al.*, 2016). Taken together, accumulating data clearly support the assumption that E2 is involved in the feedback regulation of piscine kisspeptins via various estrogen receptors.

A relatively new neuropeptide found to be involved in fish reproduction is Neurokinin B (NKB, encoded by the gene *tac3*). NKB is a member of the tachykinin peptide family. The mammalian NKB is unique in that its prepro-hormone encodes a single mature peptide, while other prepro-tachykinins encode two mature peptides. Mammals also have one high affinity receptor for NKB (NKBR/NKR3). In contrast, fish have up to three NKB receptors and two genes encoding NKB. Importantly, prepro-tachykinin3 of fish matures into two peptides. Because the additional peptide appears only in fish and frogs, it was designated neurokinin F (NKF; Fig. 1) (Biran *et al.*, 2012). Moreover, while kisspeptin and NKB are co-expressed by the same neurons in the mammalian hypothalamus, the piscine kisspeptin and NKB are expressed by different neuronal subsets of the fish hypothalamus (Ogawa *et al.*, 2012). NKB-R are expressed in LH but not FSH cells, suggesting regulation of final oocyte maturation by NKB via LH surge (Biran *et al.*, 2014). *In vivo* administration of NKB/NKF peptides increased reproductive functions in zebrafish, tilapia, goldfish and striped bass (Biran *et al.*, 2012, 2014; Zmora *et al.*, 2017). However, *tac3* gene products in carp do not play a role in LH synthesis at the pituitary level, but may serve as novel stimulators for prolactin and somatolactin synthesis.

The Pituitary and its Gonadotropins

As in other vertebrates, the regulation of fish reproduction involves the synthesis and secretion of hormones from the adenohipophysis, including FSH (GTH-I), LH (GTH-II), growth hormone (GH), thyroid-stimulating hormone (TSH) and adrenocorticotrophic hormone (ACTH), with FSH and LH serving as the key regulators of gonadal development and function. FSH and LH are heterodimeric hormones with a distinct β subunit and a common α subunit, which is also common to TSH). Over the years, gonadotropin subunit genes were isolated in more than 56 fish species from at least 14 teleost orders, allowing a vast characterization of fish gonadotropin synthesis and release. Signals from hypothalamic neurohormones and gonadal steroids are integrated in

gonadotrope cells to regulate synthesis and release of both gonadotropins. Nonetheless, GnRH regulation of FSH synthesis and release is less clear than that of LH (Zohar *et al.*, 2010; Yaron *et al.*, 2003).

As previously described, there are two main modes of gonadal development in fish. Synchronous gonadal development is accompanied by a clear duality of gonadotropin secretion; while the adenohypophysis of immature salmon contains mainly FSH cells, the adenohypophysis of sexually mature rainbow trout contains numerous LH-producing cells. In addition, only FSH is released into the blood of immature coho salmon, with increased levels during the gonadal recruitment step, and reduced levels towards final oocyte maturation and spawning. While both gonadotropins induce E2 secretion, LH is more potent than FSH in raising 17 α ,20 β dihydroxy-4-pregnen-3-one (DHP) levels from post vitellogenic oocytes (Swanson, 1991). However, in carp, LH alone is sufficient to regulate both vitellogenesis and final oocyte maturation while FSH may have another, yet undefined role. In contrast, both FSH and LH are synthesized and released during all stages of reproduction in multi-spawning fish with asynchronous ovaries like the gilthead seabream, goldfish and tilapia (reviewed by Levavi-Sivan *et al.* (2010); Yaron *et al.* (2003)). These differences are probably due to the need to regulate the development of several oocyte generations in parallel. In this situation, the differential regulation of each oocyte generation may be attributed to differences in the expression of gonadotropin receptors.

The fish FSH and LH receptors are GPCRs belonging to the Class A of rhodopsin-like receptors. Mammalian FSHR and LHR show very high selectivity to their cognate ligands, leading to functional specificity. However, ligand-receptor promiscuity was shown in several fish species. Structural modeling combined with *in vitro* assays of gonadotropin receptor activation have demonstrated that in some fish species, FSHR may bind both FSH and LH, while in almost all fish species tested, LHR is highly specific for LH (Aizen *et al.*, 2012). Concomitant with their importance in induction of ovarian steroidogenesis, gonadotropin receptors are expressed by follicular cells of the ovary (theca and granulosa cells) and by interstitial and nurse cells of the testis (Leydig and Sertoli cells) (Yaron and Sivan, 2006).

Gonadal steroids transmit their feedback to regulate the synthesis and release of FSH and LH. This feedback can be of a positive or negative nature, depending on the reproductive state of the fish. Gonadectomy in sexually mature goldfish, catfish, Atlantic croaker, bass and salmonids results in increased LH secretion, while treatment with gonadal steroids may reverse this effect. Nevertheless, during earlier stages of gonadal development, gonadal steroids can induce LH β subunit expression and protein levels (Levavi-Sivan *et al.*, 2010; Yaron *et al.*, 2003). More anatomical work is required to understand whether these effects are direct or indirect.

LH acts on the ovarian follicle to produce DHP, the maturation-inducing Hormone, (MIH) in most fishes. The dramatic increase in the capacity of post vitellogenic follicles to produce DHP in response to LH is correlated with a decrease in P450c17 (*P450c17-I*) and P450 aromatase (*pP450arom*) mRNA and increase in the novel form of P450c17 (*P450c17-II*) and 20 β -hydroxysteroid dehydrogenase (*20 β -HSD*) mRNA.

The Gonads and Their Steroids

Most fish species used in research and aquaculture are gonochoristic. Therefore, a sexually mature fish would have either a functional testis (male) or a functional ovary (female). In most gonochoristic fish, FSH and LH stimulate the synthesis of three key sex steroids: E2 serves as the principal estrogen and stimulates germ-cell proliferation and growth and vitellogenesis; 11 ketotestosterone (11-KT) serves as the central androgen that regulates spermatogenesis and spermiogenesis; DHP regulates final oocyte maturation and ovulation in females as well as spermatozoa maturation and spermiation in males (Yaron, 1995). In addition, DHP is involved in the meiosis onset of ogonia in the ovary and of spermatogonia in the testis. Androgens and E2 (under FSH) are involved in the appearance of lipid droplets in previtellogenic oocytes. It is noteworthy that higher vertebrates utilize testosterone and not 11-KT as their main androgenic hormone. These pathways are regulated in parallel to the above-mentioned feedback regulation of gonadal steroids on reproductive functions of the hypothalamus and pituitary (Fig. 2).

Male

In spermiogenesis, non-functional sperm undergo the process of sperm maturation to become mature spermatozoa, fully capable of vigorous motility and fertilization. These processes are mainly controlled by sex steroid hormones. Spermatogonial renewal is controlled by E2 through the expression of platelet-derived endothelial cell growth factor. The proliferation of spermatogonia toward meiosis is initiated by 11-KT, which is produced by FSH stimulation. 11-KT prevents the expression of anti-Müllerian hormone (AMH), which functions to inhibit proliferation of spermatogonia and induce expression of activin B, which functions in the induction of spermatogonial proliferation. Meiosis is induced by DHP through the action of trypsin. DHP also regulates sperm maturation through the regulation of seminal plasma pH. Gonadotropic stimulation of Leydig cells in the testis induce the synthesis and release of 11-KT, which leads to the activation of Sertoli cells, resulting in stimulation of spermatogenesis. With the advancement of spermatogenesis, 11-KT levels start to decline and DHP levels rise, leading to induction of spermiogenesis. In some fish species, DHP was shown to further regulate sperm motility (Miura and Miura, 2011; Schulz *et al.*, 2010) (Fig. 2).

Female

In the case of female fish, the endocrine roles of gonadal steroids are more complex; alongside their roles in feedback regulation and gonadal development, gonadal estrogens induce the synthesis and release of vitellogenin (VTG), the primary storage protein in fish oocytes, by the female liver (Lubzens *et al.*, 2017). In fish with synchronous ovaries, theca cells of the follicle respond to FSH to produce testosterone, which is then aromatized into E2 by the granulosa cells. E2 stimulates the production of VTG and in parallel

Fig. 2 Endocrine control of spermatogenesis A schematic diagram summarizing the possible control mechanisms of spermatogenesis in the Japanese eel. FSH, follicle-stimulating hormone; LH, luteinizing hormone; 17 α ,20 β -DHP, 17 α ,20 β -dihydroxy-4-pregnen-3-one; PD-ECGF, platelet-derived endothelial cell growth factor; AMH, anti-Müllerian hormone; CAII, carbonic anhydrase; eSRS, spermatogenesis related substances. Reproduced from Miura, C., Miura, T., 2011. Analysis of spermatogenesis using an eel model. *Aqua-Biosci. Monogr.* 4, 105–129.

regulates its accumulation in the yolk. Following the vitellogenic growth of the oocyte, FSH levels decline concurrently with the rise in LH levels. This leads to shifts in steroidogenesis that leads the ovary to produce mainly DHP (Yaron, 1995).

In addition to the classic genomic mechanism of steroid action mediated by activation of intracellular nuclear receptors, there is now extensive evidence that steroids also activate receptors on the cell surface to initiate rapid intracellular signaling and biological responses that are often non-genomic. Two recently discovered novel proteins with seven-transmembrane domains, GPCR30 (GPR30), and membrane progesterin receptors (mPRs), have the ligand binding and signaling characteristics of estrogen and progesterin membrane receptors, respectively. During the first phase – at the end of vitellogenic oocyte growth – the ovarian follicles produce large amounts of estrogens and minor quantities of progestins, resulting in activation of the inhibitory pathway regulating oocyte maturation, but not the stimulatory pathway. The estrogens act through GPR30 to activate a stimulatory G protein (Gs), resulting in stimulation of adenylyl cyclase activity and increases in cAMP production. The high levels of cAMP maintain meiotic arrest of fish oocytes, possibly through downstream signaling molecules such as protein kinase A. In addition, estrogens upregulate GPR30 expression to potentiate the inhibitory pathway and down-regulate mPR α expression to block the stimulatory one, through activation of GPR30 via unknown pathways. As a result, the oocytes remain in meiotic arrest. In the second phase, the steroidogenic pathway is switched to the production of progestins and estrogen production is declined. At the same time, progestins, through mPR α , cause down-regulation of GPR30 expression, which together with the reduction in estrogen levels, causes suppression of the inhibitory pathway. Progesterin binding to mPR α results in activation of an inhibitory G protein (Gi) decreasing adenylyl cyclase activity and cAMP levels, leading to inhibition of protein kinase A, thereby releasing the oocyte from meiotic arrest and allowing oocyte maturation to proceed (Thomas, 2012).

Genome Editing Era in Fish Reproduction

The emergence of the novel methods of transcription activator-like effector nucleases (TALEN) (Bedell *et al.*, 2012) and clustered regularly interspaced palindromic repeats-associated (CRISPR)/Cas9 (Gagnon *et al.*, 2014) systems, commenced a technological revolution in fish genome editing, allowing reverse genetics in fish. These methods are now applicable in several fish species of commercial importance, including Atlantic salmon (Edvardsen *et al.*, 2014), channel catfish (Khalil *et al.*, 2017), Nile tilapia (Wu *et al.*, 2016), sea lamprey (Square *et al.*, 2015) and model fish species zebrafish and medaka (Bedell *et al.*, 2012; Gagnon *et al.*, 2014; Luo *et al.*, 2015). These tools have already provided some exciting findings regarding the endocrine regulation of fish reproduction.

At the hypothalamic level in zebrafish, no phenotypes were found in fish carrying single or double mutations in genes encoding kisspeptin ligands or their receptors (Tang *et al.*, 2015). Similarly, no phenotypes were identified in GnRH3 mutant zebrafish, and even triple knockout fish for both kisspeptin ligands and GnRH3 resulted in normal reproductive development (Spicer *et al.*, 2016; Liu *et al.*, 2017). These findings strongly challenge the current dogma of neuroendocrine regulation of fish reproduction.

At the pituitary level, zebrafish carrying homozygous mutation in the gene encoding FSH β -subunit, display delayed gonadal maturation; and mutants in the gene encoding LH β -subunit show normal gonadal development but fail to spawn and hence are infertile (Zhang *et al.*, 2015). Double mutant zebrafish for both gonadotropins or both gonadotropin receptors develop an

infertile all-male population phenotype. However, while FSHR mutant females are infertile, FSHR mutant males show no significant phenotype (Chu *et al.*, 2015).

At the gonadal level, “loss of function” mutations in the zebrafish aromatase gene resulted in an all-male phenotype (Lau *et al.*, 2016); and mutating the nuclear progesterone receptor in zebrafish leads to female infertility due to ovulation failure with no reproductive phenotype in males (Tang *et al.*, 2016).

Taken together, these findings demonstrate the high importance and strength of genomic editing in fish. Nevertheless, it also highlights the need for additional knockout lines in other commercially important fish models.

Concluding Remarks

As in other vertebrates, in fish, endocrine regulation of reproduction is governed by the HPG axis. In the current article, we briefly reviewed the endocrine components of the axis with emphasis on the unique and different characteristics of these components. Taken together, the data presented show the high evolutionary importance of fish as model organisms for endocrine research in the reproductive field; they are an exciting model for studying vertebrate reproduction. Moreover, some features in the piscine HPG axis may provide explanations to phenomena that cannot be addressed in higher vertebrates. For example, the anatomical separation between FSH and LH enables the characterization of regulatory pathways for each gonadotropin, while their co-expression in mammals would hamper such efforts.

Finally, there is no doubt that novel genomic tools will significantly advance endocrine research in fish, which will lead to important breakthroughs. Nevertheless, adopting these methodologies should be advanced in concert with development of additional and more classical endocrine tools, such as specific hormone ELISAs, antibodies and anatomical research.

Endocrine Control of Reproduction, Birds

Jenny Q Ouyang, University of Nevada, Reno, NV, United States

Introduction

Birds *aves* are oviparous (egg-laying) vertebrates. Reproduction is an activity that consists of multiple stages in their life-history, which include maturing of the gonads, courtship and mating behaviors, nest building, female egg-laying, incubation, and feeding of the nestlings (Lack, 1968). Reproduction is followed by the next life-history stage, e.g., molt (the shedding and replacement of feathers), which require the regression of the reproductive organs. Therefore, the control of reproduction is an intricate and time-dependent process that needs to be responsive to the external environment. Hormones integrate internal and external conditions, mediating and controlling reproductive processes (Hau and Goymann, 2015).

Reproductive physiology and behavior of birds are governed by the hypothalamic-pituitary system (HPS), which sends signals to the rest of the body to initiate and end reproductive activities. Thus, this article will start with the role of the HPS and associated hormones, with a focus on two antagonistic neurohormones in the hypothalamus. Then it will highlight the endocrine control of ovulation, incubation, and parental care activities and conclude with a brief discussion of the endocrine systems associated with reproduction in response to seasonal and environmental change.

Hypothalamic-Pituitary System

The HPS controls reproductive activity in birds. Neurons in the hypothalamus integrate external (light, temperature, food availability) and internal (water and ion balance, nutrition, body condition) cues to help the animal make informed decisions about when to be reproductive (Fig. 1). Fig. 1 also summarizes the rest of the HPS with information about control and regulation. Gonadotropin-releasing hormone (GnRH), gonadotropin-inhibiting hormone (GnIH), hypothalamic vasoactive intestinal peptide (VIP), and arginine vasotocin (AVT) are neurohormones that play important roles in the brain. Neurohormones are transmitted through axons and released in the median eminence. They are then released directly into the anterior pituitary through the blood. AVT is transmitted through axons and released at the posterior pituitary (Oksche, 1978). Anterior pituitary hormones in birds include luteinizing hormone (LH), follicle stimulating hormone (FSH), prolactin (PRL), thyrotropin (TSH), corticotrophin (ACTH), and growth hormone (GH).

GnRH and GnIH

GnRH regulate most reproductive behaviors of birds. There are two forms of this peptide. GnRH-I was first discovered in mammals and then isolated from chickens (Miyamoto *et al.*, 1982). Subsequently, this peptide was found in a wide array of species, including ducks, other galliformes, doves, and songbirds (Bentley *et al.*, 2006). The second form of GnRH is GnRH-II, which was first isolated

Fig. 1 A brief outline of the neuroendocrine mechanisms controlling reproduction in birds. Neurohormones in the hypothalamus integrate external cues, such as light or availability of mates, with internal cues, such as body condition. Gonadotropin-inhibiting hormone (GnIH) could be stimulated by melatonin and/or stress which directly inhibit reproductive activities. Gonadotropin-releasing hormones (GnRH) stimulates the pituitary to release thyrotropin (TSH), luteinizing hormone (LH), and follicle stimulating hormone (FSH), which all have actions on the gonads for regulating ovulation. Prolactin (PRL) can also stimulate and regulate a suite of reproductive behaviors. Finally, sex steroids are released from the gonads and regulate sexual and parental behaviors.

in the chicken (Miyamoto *et al.*, 1984). There is good evidence that GnRH-I directly stimulates LH and FSH release in vitro and in vivo (Hattori *et al.*, 1986) in chicken and in quail. GnRH-II's activity on LH and FSH is almost equal to that of GnRH-I, but is more noticeable on LH than FSH. GnRH is usually higher in ovulating birds because of its stimulating role on LH and the pre-ovulatory LH surge. GnRH-I's role is more direct on LH and FSH whereas GnRH-II seems to be more involved with sexual behaviors, such as aggression, courtship, and copulation. For example, GnRH-II enhances copulation when females are exposed to male song (Maney *et al.*, 1997).

GnIH may act as the antagonist of GnRH in the hypothalamus. GnIH was first found in the paraventricular nucleus in quail with neurons that project into the median eminence (Tsutsui *et al.*, 2010). Therefore, it can directly affect anterior pituitary hormone release. Since its discovery, GnIH has been found in the brains of many species, including songbirds. GnIH has been shown to inhibit gonadal development by decreasing FSH and LH (Ubuka *et al.*, 2006). This inhibition has direct effects on spermatogenesis and gonadal growth; specifically, LH in avian species stimulates the production of testosterone (T) in the Leydig cells. Injecting GnIH to mature birds can induce apoptosis of testicular tissue and regression of the gonads. Moreover, GnIH can inhibit copulatory behavior even if females are exposed to male song.

Ovulation, Incubation, and Parental Care

Ovulation

The ovaries of female birds contain developing follicles in a sequence with the largest follicle ovulated at regular intervals. FSH stimulates the maturation of these germ cells. Due to the regularity in follicle development, most birds lay one egg per day during the breeding season, although it is possible for females to pause laying or skip days in the laying sequence. Birds can also lay more than one group (clutch) of eggs during the breeding season, e.g., sparrows in the northern latitudes lay only one clutch but in southern latitudes can have up to three (Baker, 1995). Determinate layers are those that lay a fixed number of eggs (e.g., some raptors) and indeterminate layers are those that continue laying for a long time (e.g., domesticated chickens). Birds have one ovary and one oviduct so only one egg can be laid at one time.

Most of studies on ovulation and oviposition have been performed in the chicken. The initiation of ovulation begins with a LH surge, or a rise in LH levels pre-ovulation. FSH during this time remains relatively constant, and PRL levels are inversely related to LH. Estradiol (E₂) also peaks with the LH peak. Progesterone (P₄) triggers the LH surge and GnRH stimulates P₄ release (Hertelendy *et al.*, 1982). Ovulation then occurs approximately 7 hours after the LH surge. The egg spends the next 24 h in the oviduct before it is laid. The next ovulation can vary between 15 and 75 min after the previous egg was laid. This strict time sequence restricts the timing of ovulation and egg-laying. Light cues are important for ovulation, i.e., most songbirds lay their egg during the morning, especially around dawn. When chickens are placed in constant light, their rhythm of egg-laying becomes free-running because they are missing external light cues (Lewis *et al.*, 2001). In addition to light, abiotic cues, such as temperature, may also play a role (Payne *et al.*, 1965).

After ovulation, the egg travels to the oviduct, where fertilization and deposition of albumen occurs. The avian oviduct is an intricate structure with specific functions, such as deposition of melanin, pigments for coloration, albumen and coating. Albumen is laid down in layers with surrounding membranes. The uterus, also known as the shell gland in birds, coats the albumen and membranes with an egg shell that differs in pigment and coloration with large intra- and inter-species variation. For example, some species of ground nesters have eggs that camouflage with the environment (Cherry and Gosler, 2010).

Egg-Laying (Oviposition)

Oviposition (egg-laying) occurs through the vagina and cloaca. AVT, mesotocin (MST) and ovarian hormones are the main molecules responsible for oviposition. The mammalian homologs of AVT and MST are arginine vasopressin and oxytocin, respectively. In birds, AVT has a greater effect than MST on uterine contractions (Saito and Koike, 1992). AVT levels increase sharply to induce contractions and decrease within minutes after the egg is laid.

Incubation

After the last egg is laid in a clutch, a period of incubation, or warming the eggs, occurs so that the embryo can develop within the egg (Drent and Daan, 1980). Depending on the species, the male, female, or both sexes will develop a brood patch, a spot of featherless skin. However, not all species form a brood patch, e.g., male emperor penguins incubate eggs with a flap of skin and their feet. The presence of eggs will often influence brood patch formation. The brood pouch skin has an enlarged organic tissue due to cell proliferation and vascularization, which facilitates the transfer of heat from the parent to the egg. The process of brood patch development is regulated through a synergism between PRL and sex steroids. In females, estrogen and P₄ are the main regulators and in males, the main regulators are androgens.

VIP stimulates the release of PRL from the pituitary. PRL usually induces the bird to incubate and maintain incubation (Buntin, 1996). Incubation behavior is thought to be maintained through tactile stimuli from the nest or the eggs. In altricial species, or species that have young that are helpless and depend on their parents for food at hatch, parental PRL remains high during incubation and remains elevated throughout chick-rearing. In precocial species, or species that have independent young at hatch,

parental PRL are high during incubation and fall after chicks have hatched (Goldsmith, 1983). In species that produce crop milk to feed the young, PRL is also essential for producing the milk.

Parental Care

After the young hatch, especially if they are altricial, comes a period of parental care, in which parents deliver food to the offspring. Recent research on the hormonal regulation of parental care offer some promising avenues for identifying possible mechanisms (Vleck and Vleck, 2011). In general, PRL and P_4 are thought to increase paternal care whereas T and corticosterone are thought to decrease paternal care (Lynn, 2016). PRL and corticosterone, the steroid hormone that increases metabolism at baseline levels and decrease reproductive behaviors at higher concentrations, are suggested to be linked and mediate parental care activities (Angelier and Chastel, 2009). Studies show that increases in corticosterone may depress PRL levels. However, a direct mechanistic pathway has not been established. Studies have shown that experimentally elevated PRL in altricial species can cause an increase in parental care behaviors (Duckworth and Sockman, 2012), but there is evidence that experimentally elevated corticosterone concentrations at the baseline range also stimulate more reproductive behaviors (Love and Williams, 2008; Ouyang *et al.*, 2013). Moreover, high corticosterone concentrations are related to foraging and parental care activities in larger seabirds (Crossin *et al.*, 2012). The effects of corticosterone on parental care are not only concentration dependent but also context dependent, e.g., according to life-history stage. For example, high corticosterone concentrations before egg-laying but low corticosterone concentrations during chick-rearing correlate with high reproductive effort and thus the number of offspring produced (Fig. 2). In conclusion, there is an environmentally context-dependent role that both corticosterone and PRL play on parental care behaviors, but experimental evidence in other taxa are missing.

About 9% of all the species of birds have a form of cooperative breeding with alloparenting at the nest. Alloparenting consists of parental activities, e.g., food delivery or nest defense, by conspecifics that are not the parents. Whether parents are reproductively competent depends on the species. For example, in some birds, male helpers have equivalent T levels as those of breeding males but in other species, helper males have lower T and smaller testes than those of breeding males (Schoech *et al.*, 2004). Oftentimes, helpers at the nest will have elevated PRL levels as compared to non-helpers.

Obligate brood parasites are species that lay eggs and have no parental care behaviors after egg-laying. Brown-headed cowbirds display a rise in circulating PRL concentrations but no incubation behaviors, which suggests that PRL binding activity in the brain is decreased (Dufty *et al.*, 2002). Often, the offspring of parasitic species display more begging behavior than the host chicks, but eggs of the parasitic cuckoo have similar yolk T than the eggs of their host (Török *et al.*, 2004).

Seasonal Reproduction

Timing of reproduction is an active area of research in avian species as they have evolved their breeding to coincide with the maximal production of offspring. Seasonal breeding is controlled by proximate and ultimate factors. Proximate factors include individual condition, and is especially critical for capital breeders that need to store up enough energy for breeding. Ultimate factors include adequate food supply, predation pressures, or climatic conditions. However, the endocrine system is secreting hormones

Fig. 2 The number of offspring (fledglings) produced by a small songbird during the breeding season was related to the change in corticosterone concentrations from March to May. March is the pre-laying period and May is the chick-rearing period. Adults with the highest March but lowest May concentrations raised the most offspring. Reproduced from Ouyang, J.Q., Sharp, P., Quetting, M., Hau, M., 2013. Endocrine phenotype, reproductive success and survival in the great tit, *Parus major*. *Journal of Evolutionary Biology* 26, 1988–1998.

to prime the individual for reproductive behaviors weeks ahead of when the chicks hatch, e.g., the time when these ultimate factors come into play. Therefore, other cues must be present.

In mid to high latitudes where photoperiod changes throughout the year, there is good evidence that photoperiod drives seasonal reproduction (Follett *et al.*, 1974). For these birds, photoperiod can be a proximate cue and provide a window that birds use to begin their gonadal growth. Even birds that live in tropical locations can respond to slight photoperiodic changes (Hau, 2001). The fine-tuning of subsequent reproductive activities can be the result of a combination of factors, such as male song inducing ovarian growth in females, ambient temperature, rainfall, or even budding on plants. Elegant experiments on temperature differences controlling the timing of reproduction show that timing is related to temperature but not absolute temperature. However, temperature shifts were not related to the circulating levels of hormones that were studied (Schaper *et al.*, 2012). For both temperate and tropical birds, the reproductive axis is probably set at ready due to photoperiodic cues and full functionality is then triggered by a combination of proximate cues that are species dependent. For example, opportunistic breeders, such as the zebra finch, are cued to rainfall and water availability (Zann *et al.*, 1995).

Photostimulation (increasing day length) triggers the growth of gonads and photorefractoriness (gonadal regression due to decreasing day length) occurs after breeding. Photorefractoriness may have evolved to minimize the cost of transporting more weight during migration or to inhibit reproduction when environmental conditions are not ideal (Wingfield *et al.*, 1995). Photostimulation causes an increase in FSH and LH, along with other gonadotropic hormones (Follett *et al.*, 1974). These hormones are still released even in castrated birds. During photorefractoriness, gonads are also not necessary. PRL may also be responsible for when birds regress their gonads after the breeding season. At the end of the breeding season, LH decreases and coincides with an increase in PRL. However, injection of PRL or blocking VIP does not cause photorefractoriness, or the non-reactiveness to differences in daylength (Dawson, 1998). PRL has been linked to molt and migration so may instead play an indirect role in life-history stage transition from breeding to molt or migration (Dawson *et al.*, 2001).

Changes in Hormones With Respect to Season and Daylength

Photoreceptors in the eye, the pineal, and the deep brain perceive light to help birds time reproductive activities. The avian eye acts as a photoreceptor but also contains a circadian clock and induces the production of melatonin (MEL). The pineal gland contains the circadian pacemaker and has photosensory cells, photopigments, and produces MEL. Lastly, deep brain photoreceptors can also perceive light information (Underwood *et al.*, 1984). GnRH and opsin, a group of light sensitive proteins, in the brain interact, suggesting direct communication between deep brain photoreceptors and GnRH neurons (Davies *et al.*, 2012).

The pineal gland of all vertebrates show daily rhythms that synthesize and produce MEL. In both diurnal and nocturnal birds, MEL is higher at night. The eyes contribute to photoperception and contribute to MEL in the blood. It has been thought that seasonal changes in MEL does not regulate reproductive effort in birds. For example, pinealectomy in birds results in individuals that are photosensitive in terms of stimulation and refractoriness (Wilson, 1991). However, increasing evidence shows that MEL is involved in some way. Injection of MEL stimulates LH and testicular size. It is hypothesized that MEL may be involved in the induction of GnIH expression, thus affecting reproductive activity (Ubuka *et al.*, 2005). Birds under constant light, sometimes due to artificial light at night, have different circadian profiles of MEL concentration and changes in reproductive activities, including advanced gonadal development (de Jong *et al.*, 2016; Dominoni *et al.*, 2013). These effects are not only dependent on light intensities but also on light spectra, possibly as a result of photoreceptor sensitivity.

Thyroidal hormones affect reproductive function but the mechanisms behind its function can be contradictory. For example, some studies find that thyroidectomy prevents gonadal regression but other studies find that photorefractoriness is accelerated (Dawson *et al.*, 2001). Thyroxine has to be present for responses to photoperiod to occur, and it could be possible that thyroid hormones affect GnRH synthesis (Bentley *et al.*, 2006). Genomic analyses reveal that gene expression of thyrotropin- β subunit peaked right after dawn, suggesting that thyroid hormones respond to changes in MEL signaling and thus are affected by photoperiod (Nakao *et al.*, 2008). Lastly, corticosterone concentrations also vary with respect to season, with higher concentrations during breeding than at other times of the year. It is possible that this elevation is due to the metabolically demanding reproductive activities (Romero, 2002).

Conclusion

Since Lack's seminar work on avian reproduction in five decades ago (Lack, 1968), we still have a relatively rudimentary understanding of the physiological mechanisms governing reproduction. Life-history traits, such as timing of breeding, egg size and number, and parental ability have received less integrated attention, especially with respect to understanding the role of hormones in regulating transitions between these life-history stages and control of these important life-history traits (Williams, 2012). Moreover, this article has focused on mechanistic and often causal effects of hormones on reproduction in birds. However, there is large, intrinsic variation among individuals, such that some females lay more eggs and some males raise more offspring. Identifying the physiological mechanisms that govern this individual variation will be key to understanding reproductive function in birds.

Hormones and Reproduction in Amphibians and Reptiles

David O Norris and Kristin H Lopez, University of Colorado, Boulder, CO, United States

The HPG Axis in Amphibians and Reptiles

Reproduction in amphibians and reptiles is tuned to environmental conditions acting through the nervous system to control the hypothalamo-pituitary-gonadal (HPG) axis. The HPG axes contain the elements described for mammals. Secretion of gonadotropins (follicle-stimulating hormone, FSH, and luteinizing hormone, LH) from the pituitary is controlled by hypothalamic gonadotropin-releasing hormone (GnRH). Release of GnRH is under the control of kisspeptins as in mammals (see [Pinilla et al. \(2012\)](#)). Gamete development is controlled by gonadotropins as is secretion of estrogenic, androgenic, and progestogenic hormones by the gonads. The latter hormones, sometimes cooperating with other hormones, are involved in development of sex accessory structures, mating behavior, and in some species gestation and parental care. Nonapeptide hormones (arginine vasotocin, AVT) and prolactin from the pituitary also affect reproduction (for detailed reviews, see [Norris and Carr \(2013\)](#) and [Norris and Lopez \(2011a,b\)](#)).

The HPG Axis of Amphibians

Reproductive endocrinology has been characterized primarily in anurans (frogs, toads) with some corroborative data from urodeles (salamanders, newts). Gymnophionid amphibians (caecilians or apodans) are similar to urodeles although the endocrine details are not well known.

The hypothalamus controls gonadotropin secretion through release of GnRH (see [Tsai \(2011\)](#)). Amphibian FSH stimulates spermatogenesis in males as well as follicle development and estrogen secretion in females. LH is responsible for androgen and progesterone synthesis by gonads as well as for stimulating oocyte maturation (see [Propper \(2011\)](#) and [Uribe Aranzabal \(2011\)](#)).

Secretion of corticosterone from the adrenals is elevated during breeding. Corticosterone can be converted to a potent androgen (5 α -dihydrotestosterone (DHT)). Very high levels of corticosterone, such as associated with stress, may inhibit reproduction.

The HPG Axis of Reptiles

Extant reptiles include squamates (lizards and snakes), turtles, crocodilians (crocodiles and alligators) and the tuatara. As in other vertebrates, reproduction is controlled by hormones: GnRH released by the hypothalamus regulates the secretion of gonadotropins by the pituitary gland. GnRH is probably released in a pulsatile manner as in mammals. The GnRH neurons of reptiles receive input from other regions of the brain that convey information about internal physiology (e.g., metabolic state) and the external environment (e.g., temperature, photoperiod, moisture, behavior of conspecifics) that influences GnRH release and thus can promote or inhibit reproductive functions. Several molecular forms of GnRH have been identified in reptiles.

Turtles and crocodilians have two distinct gonadotropins homologous to those found in other vertebrates: an FSH-like hormone that promotes gamete development and an LH-like hormone that controls gonadal steroidogenesis and gamete release. In contrast, squamates possess a single FSH-like form that performs both the gametogenic and steroidogenic functions (see [Lovem \(2011\)](#) and [Taylor and DeNardo \(2011\)](#)).

The gonadotropins bind to receptors in the gonads (testes and ovaries) of adults and promote synthesis of gonadal steroids – estrogens, androgens including testosterone, and progesterone. These steroids influence reproductive structures, functions and behaviors, and exert feedback to the hypothalamus and/or pituitary to regulate gonadotropin secretion. Most current knowledge of the neuroendocrine control of reproduction in reptiles comes from detailed studies of the green anole lizard, *Anolis carolinensis* (see [Johnson and Wade, \(2011\)](#)), but many gaps in our understanding remain.

Reproductive Cycles

A comprehensive assessment of reproductive cycles for amphibians and reptiles is available ([Norris and Lopez, 2011a,b](#)) and is summarized here. Most amphibians and reptiles become reproductively active only once a year but may produce multiple broods in a single breeding season. Reproductive cycles may occur in two forms with respect to hormonal patterns ([Fig. 1](#)). In the associative or prenuptial pattern, gonadal steroid levels are greatest during mating. Other species exhibit a dissociated or postnuptial pattern where gonadal steroids are lowest during mating.

Environmental factors operating through the brain and pituitary are important in regulating the timing of breeding. These factors include rainfall, temperature, and photoperiod. Additionally, social cues may influence hormone levels and fine-tune reproductive events.

Fig. 1 (A) Associated (prenuptial) and dissociated (postnuptial) reproductive patterns. Mating occurs at the peak of gonadal activity in species exhibiting the associated pattern (B), whereas mating occurs when gonadal activity is low in the dissociated pattern (C). Reprinted with permission from Norris, D.O., Carr, J.A., 2013. *Vertebrate Endocrinology*, fifth ed. San Diego, CA: Academic Press (Elsevier).

Reproductive Cycles in Amphibians

Because of their moist skin, adult amphibians usually occur in aquatic habitats (rivers, lakes) or moist terrestrial habitats. A few species are adapted to deserts (e.g., spadefoot toads). Life history patterns are summarized in Fig. 2. Breeding may occur in spring or autumn, depending on the species. Terrestrial amphibians experience a “water drive” controlled by prolactin that causes mature adults to seek water where they mate and deposit their eggs.

Although the basic endocrinology of all amphibians is similar, there are major life history and reproductive differences among the three extant orders: anurans (see Rastogi *et al.* (2011)), urodeles, and gymnophionids (see Norris (2011)). Fertilization is internal in urodeles and gymnophionids whereas it is external in the vast majority of anurans. Typically, sexes are separate and hermaphroditism is extremely rare. Parthenogenesis (complete development of unfertilized eggs) has been described only in interbreeding ambystomid salamanders (Norris, 2011).

Steroids secreted by the gonads affect sex accessory structures (see Sever and Staub (2011)), reproductive behaviors, spermatogenesis, and oogenesis including secretion of the estrogen-dependent egg precursor protein, vitellogenin, by the liver.

Anuran cycles

Anurans mostly lay eggs in the water, and males grasp the females (amplexus) and fertilize eggs while they are being laid. Fertilized eggs hatch as a fish-like aquatic larval stage (tadpole) followed some time later by a dramatic anatomical and biochemical transformation (metamorphosis) to a terrestrial or semi-terrestrial adult. Metamorphosis is directed by thyroid (HPT) and adrenal (HPA) axes (Norris and Dent, 1989; Denver, 1996; Shi, 2000). A few species retain their eggs within or upon their bodies and give birth to metamorphosed juveniles (viviparous). Some lay eggs in water but metamorphosis occurs in the egg prior to hatching.

Fig. 2 Amphibian reproductive cycles. Life cycles vary from totally aquatic without metamorphosis (paedomorphic or neotenic) to production of terrestrial eggs or live-bearing (viviparity). In some cases metamorphosis is completed within the egg and a miniature adult rather than a larva appears at hatching. Reprinted with permission from Norris, D.O., Carr, J.A., 2013. *Vertebrate Endocrinology*, fifth ed. San Diego, CA: Academic Press (Elsevier).

Urodele cycles

Male salamanders and newts produce gelatinous structures called spermatophores with sperm deposited at their tips. A receptive female is induced to pass over the spermatophore and take the packet of sperm into her cloaca. Sperm are stored in the spermatheca associated with the oviduct until ovulation. The eggs are fertilized with stored sperm as they are shed, often in the absence of males. Urodeles generally produce aquatic larvae although they are more advanced in development at hatching than anurans (e.g., all 4 limbs emerge prior to hatching). Larvae are characterized by external gills for respiration. Typically, the larvae undergo metamorphosis to produce a semi-aquatic or terrestrial adult. In some species the aquatic larva doesn't undergo metamorphosis and becomes sexually mature, a condition referred to as paedomorphosis. Females of a few species (genus *Salamandra*) retain the fertilized eggs that develop into larvae or fully metamorphosed young within the oviducts.

Gymnophionid cycles

Adult gymnophionid amphibians are completely terrestrial. They are oviparous or live-bearing and exhibit internal fertilization accomplished by a male intromittant organ, the phallodeum. The fertilized eggs are either laid in burrows on land or develop within the oviducts of the females. Their reproductive endocrinology, however, is virtually unknown.

Reproductive Cycles in Reptiles

Although amphibians and reptiles share characteristics of their reproductive biology with other vertebrates, reptiles differ from amphibians in several regards. Reptilian reproduction is liberated from an aquatic environment. The amniotic egg appeared first in reptiles, allowing females to lay their eggs on land. Compared to the prodigious quantity of eggs produced by most amphibians, reptiles typically produce a few large eggs well-provisioned with yolk. Fertilization is internal, usually aided by a male copulatory organ. Because development of the fertilized egg begins within the maternal reproductive tract, the embryo can be retained *in utero* for variable periods of time. Squamate reptiles exhibit a wide spectrum of egg-retention strategies, from a period of development of the shelled egg in the uterus (oviparity) to complete gestation supported by a maternal placenta and birth of a fully-developed neonate (viviparity). Although sex is genetically determined in many reptiles, incubation temperature determines the sex of crocodilians and most turtles, and thus hatchling sex varies with nest temperature and egg position within the nest. Finally, all-female (parthenogenetic) species of some squamate reptiles reproduce without the genetic contribution of males.

The reproductive system of reptiles is responsive to endocrine and paracrine factors, and also is influenced by environmental cues including temperature, photoperiod, rainfall and the behaviors of conspecifics. Most reptiles exhibit a seasonal cycle of reproduction; even tropical species usually confine reproductive activity to a portion of the year. Individuals in continuously breeding populations may have asynchronous cycles. The annual female cycle involves one or more extended bouts of ovarian growth as oocytes accumulate yolk (vitellogenesis), after which females mate, ovulate, and lay their eggs. This cycle is extended in viviparous species as gravid females retain their developing embryos *in utero* and give birth to live young. The male reproductive cycle includes spermatogenesis (sperm formation), testicular secretion of testosterone and other sex steroids, and the expression of behaviors related to reproduction (territoriality, courtship, mating). In temperate species, testes regress and spermatogenetic activity ceases during the winter dormancy. Individual reptiles, especially females, may skip one or more reproductive cycles, so a given population may include both reproductively active and inactive adults.

Squamates

Current knowledge of squamate reproductive cycles is based largely on studies of temperate species despite the abundance of understudied tropical species. Most species of lizards and snakes exhibit a seasonal reproductive cycle (see [Lovern \(2011\)](#) and [Taylor and DeNardo \(2011\)](#)). In temperate zones, eggs are laid in the spring and the young hatch at a time when food resources are most abundant to support growth and survival. Temperate zone squamates usually display the prenuptial pattern of gametogenesis with maximal steroid hormone secretion preceding spring mating and ovulation. However, some viviparous lizards mate in the fall and give birth the following spring. Tropical squamates may time their reproductive periods to the wet or dry season, whereas some reproduce throughout the year, although no individuals breed continuously.

In females, estradiol is high during vitellogenesis and follicular growth. Progesterone is elevated between ovulation and oviposition, and in viviparous species progesterone remains high in gravid females. Testosterone is present in low concentrations in females but may be raised during the breeding season.

Testosterone is elevated in males during spermatogenesis and in most species during courtship and mating, regardless of whether mating activities coincide with spermatogenesis. Testosterone is low in nonbreeding males and during testicular regression in temperate species.

Turtles

Turtles exhibit an annual cycle of gametogenesis and breeding (see [Blanvillain et al. \(2011\)](#)). However, the frequency of reproductive bouts varies among species and individuals. For example, the painted turtle *Chrysemys picta* lays only one clutch per year, whereas the massive leatherback sea turtle (*Dermochelys coriacea*), which oviposits several clutches per reproductive season like other sea turtles, lays up to 10 clutches annually. However, individual female sea turtles reproduce every 1–4 years.

Terrestrial turtles in temperate zones exhibit an annual cycle of mating, nesting and gonadal activity. For example, the desert tortoise lays a single clutch in the spring or early summer. Follicular growth begins again in late summer and females enter winter hibernation with a full complement of yolked follicles that are ovulated the following spring. Testes also recrudescence in late summer and testosterone levels rise postnuptially. Mating occurs in the fall or after emergence from winter hibernation. Spermatozoa are stored in the epididymides during winter hibernation; sperm from fall matings may also be stored in the female reproductive tract. Male testosterone levels are low during the spring mating season. In females, progesterone levels rise during ovulation and may promote the secretion of albumin and shell around each ovulated egg prior to oviposition.

Sea turtles live and mate in the water but nest on land; their reproductive pattern is prenuptial. Reproduction is coupled with an extensive migration from feeding grounds to natal nesting beaches that may be thousands of miles away. In males, testosterone rises and spermatogenesis begins in the fall, before mating and migration. Follicular growth also starts in the fall, with rising estradiol levels stimulating a months-long period of vitellogenesis and ovarian growth. Testosterone in females rises in winter and remains elevated during migration and mating. These steroids decline during nesting. Progesterone peaks sharply at ovulation. In both sexes, gonadal steroids are lowest during the return migration. A unique feature of olive ridley and Kemp's ridley sea turtles is the aggregation of thousands of nesting females on a beach; this phenomenon is known as *the arribada*.

Crocodylians

Much of our knowledge of crocodylian reproductive endocrinology is based the American alligator, *Alligator mississippiensis* (see [Milnes \(2011\)](#)). Crocodylians inhabit temperate and tropical environments; all exhibit seasonal cycles with temperate species responding to photoperiod and temperature, and tropical species timing reproduction to rainfall and food availability ([Fig. 3](#)).

Development of the large yolky eggs takes several months. In female *A. mississippiensis*, vitellogenesis takes place in the fall when estradiol levels rise post-reproductively. After winter dormancy, a second phase of yolk deposition is accompanied by peak estrogen levels. Testosterone rises in females during the breeding season. Estradiol and testosterone then decline and progesterone rises at ovulation; progesterone later drops as females begin to lay their eggs within nests they have built of vegetation and mud near the water. In tropical species oocyte development takes place during the dry season immediately before breeding activities begin.

In males, after a period of quiescence in which the testes are spermatogenetically inactive, recrudescence occurs about four months before the mating season. Spermatogonia divide, enter meiosis and progress to produce mature spermatozoa by the beginning of mating activities. Testosterone remains high during spermatogenesis and the ensuing courtship and mating season, after which circulating levels decrease as the testes regress.

Fig. 3 Comparison of reproductive cycles of tropical and temperate crocodilians. Recrudescence refers to renewal of spermatogenesis/oogenesis following a previous reproductive period. Reprinted with permission from Norris, D.O., Carr, J.A., 2013. *Vertebrate Endocrinology*, fifth ed. San Diego, CA: Academic Press (Elsevier).

Gonadal Aspects of Reproduction

Details of spermatogenesis and testicular structure were reviewed recently for amphibians by [Propper \(2011\)](#) and for reptiles by [Kumar et al. \(2011\)](#). Ovarian and oviductal cycles were reviewed for amphibians by [Uribe Aranzabal \(2011\)](#) and for reptiles by [Jones \(2011\)](#).

Amphibian Gonads

The structure and function of amphibian testes and ovaries provided here is based on reviews by [Propper \(2011\)](#) and [Uribe Aranzabal \(2011\)](#).

Testes of amphibians

Spermatogenesis is of the cystic type in all amphibians as described for fishes, although the testes of anurans are sometimes described as consisting of seminiferous tubules. Urodele and gymnophionid testes are organized into distinct lobules, each containing several ampullae. In urodeles spermatogenesis proceeds synchronously within an ampulla, whereas it is asynchronous in gymnophionids.

Leydig cells (=lobule boundary cells) are located at the periphery of the ampullae and secrete testosterone and DHT in response to LH. These androgens stimulate development and secretion of the vasa deferentia and reach peak levels during sperm storage. They also are responsible for development of the nuptial pads used to hold females during copulation ([Fig. 4](#)).

Ovaries of amphibians

Oogenesis in amphibians is of the indeterminate type; that is, germ cells (oogonia) produce new oocytes annually. The nucleus of the oocyte begins meiosis but is arrested as a germinal vesicle until ovulation. Folliculogenesis begins with meiosis as each oocyte becomes surrounded by follicle cells that, under the stimulation of FSH, differentiate into thecal and granulosa cells. FSH also stimulates oocyte growth.

Granulosa cells are the major source of steroid hormones: androgens (testosterone, DHT, and androstenedione) and progesterone stimulated by LH, and estrogens (estradiol, estrone) stimulated by FSH. Ovaries also produce some deoxycorticosterone (DOC). High levels of circulating testosterone occur in some females ([Fig. 4](#)). Secretion of estrogens stimulates production of

Fig. 4 Hormonal cycles in male and female salamanders, *Pleurodeles waltli*. (A) Seasonal changes in total androgens (testosterone, DHT, androstenedione) in captive males. SSC represents development of thumb pads, which are androgen-dependent secondary sex characters used in amplexus with females. Reprinted with permission from Garnier, D.H., 1985. Androgen and estrogen levels in the plasma of *Pleurodeles waltli* Michah. During the annual cycle I. Male cycle. Gen. Comp. Endocrinol. 58, 376–385 (Elsevier). (B) Total androgen (solid circles and solid line) are much higher than estradiol levels (triangles and dotted line) in females. Nevertheless, total androgens are much lower than in males (Fig. 4(A)). Ratio of estradiol to androgens is shown (open circles). Reprinted with permission from Garnier, D.H., 1985. Androgen and estrogen levels in the plasma of *Pleurodeles waltli* Michah. During the annual cycle II. Female cycle. Gen. Comp. Endocrinol. 60, 414–418 (Elsevier).

the yolk protein precursor vitellogenin by the liver. Vitellogenin travels through the blood to the ovary where it is used to make yolk proteins that are incorporated into the developing oocyte.

Ovulation is controlled by LH. Germinal vesicle breakdown is induced by LH acting through ovarian progesterone. Egg laying or birth of live young occurs in the spring whereas mating may occur in either fall or spring in different species.

Oviductal hypertrophy and secretion is stimulated by estrogens (Fig. 5). In oviparous species, the oviduct is responsible for secretion of the jelly coat that surrounds each egg. Progesterone-primed oviducts respond to AVT by contracting and expelling the coated eggs. In urodeles with internal fertilization, the eggs are fertilized prior to application of the jelly coat. In anurans with external fertilization, the eggs are fertilized prior to entering the water where the jelly coating swells and prevents entry of additional sperm.

Gonadal Aspects of Reproduction in Reptiles

The structure and function of reptilian testes and ovaries provided here is based on reviews by Kumar *et al.* (2011) and Jones (2011).

Testes of reptiles

The testes are paired oval organs that, as in other vertebrates, have two major functions: production of sperm (spermatogenesis) and synthesis of gonadal steroid hormones. Spermatogenesis occurs within seminiferous tubules that are tightly packed within the testes. Sertoli cells form the somatic epithelial component of the seminiferous tubules. They extend from the basal surface to the lumen of the tubule and maintain the blood-testis barrier. These “nurse cells” provide physical support and nourishment for the developing germ cells, which advance in stages of spermatogenesis from the basal to luminal surface.

The steroidogenic Leydig cells are located in the stroma between adjacent coils of seminiferous tubules. Androgens secreted by Leydig cells enter the peripheral circulation and act to develop and maintain sex accessory structures and promote mating behaviors. Testosterone is elevated during spermatogenesis in most species during the breeding season (Fig. 6), regardless of whether mating activities coincide with spermatogenesis. In temperate species, testosterone is low in nonbreeding males and during testicular regression. Sertoli cells also produce androgens that may act peripherally to induce reproductive behaviors as well as locally within the seminiferous tubules to promote spermatogenesis. These two androgen sources enable separate control of gamete production and reproductive behavior that may allow the uncoupling of spermatogenesis and mating in species with post-nuptial breeding. The

testis is also the site of synthesis and action of estrogens. Estrogens are inhibitory to spermatogenesis in squamates and turtles, and thus may play a role in seasonal testicular quiescence.

Testicular function is regulated by gonadotropins. FSH promotes spermatogenesis, and LH regulates testicular steroidogenesis in turtles and crocodilians. In squamates, testicular functions are all regulated by a single FSH-like gonadotropin. Our understanding of the precise roles of reptilian gonadotropins is limited, as many studies are based on effects of mammalian gonadotropins, and data on plasma concentrations of reptilian gonadotropins are scarce. Stress-induced glucocorticoids inhibit plasma androgen levels as well as spermatogenesis in some reptiles.

Testicular size changes throughout the year in most male reptiles, particularly in temperate species. In response to environmental cues such as decreased temperature, shorter day-length and lower rainfall/food availability, spermatogenesis shuts down and the testes shrink. Inhibition of Leydig cell steroidogenesis may or may not accompany season testicular regression.

Sperm can remain viable for many months in the male reproductive system (epididymides) or female reproductive tract.

Ovaries of reptiles

Reptilian ovaries are paired, hollow oval structures (elongated in snakes) within the dorsomedial body cavity, loosely attached by a mesovarium to the dorsal body wall. Ovarian size varies greatly throughout the year depending on the number and size of ovarian

follicles present. Each follicle, the functional unit of the ovary, contains an oocyte surrounded by an enveloping layer of support cells. Very little connective tissue stroma is present.

Females can produce new oocytes from oogonial stem cells throughout their lives, similar to fishes and amphibians but unique among amniotic vertebrates. Mitotically dividing oogonia are clustered in a species-specific number of germinal beds located on the dorsal surface of the ovary. Newly-formed oocytes enter meiosis and become individually surrounded by granulosa cells. An external follicular layer, the theca, consists of an inner steroidogenic layer and an outer protective capsule. Under the influence of estradiol secreted from the developing follicles, the liver produces vitellogenin that serves as the precursor for yolk proteins. The telolethical oocytes accumulate large quantities of yolk during follicular growth. The ovaries secrete androgens in low amounts but in some species testosterone is significantly elevated during the mating season.

Ovulation of mature oocytes is likely under the influence of LH as in other vertebrates, with the exception of squamates. Granulosa cells of the postovulatory follicle transforms into a corpus luteum and secrete progesterone. Luteal progesterone peaks during the periovulatory period and remains elevated while females are gravid, dropping sharply at oviposition or birth of the young. Progesterone suppresses motility of the oviducts and probably inhibits follicular growth and vitellogenesis via feedback inhibition of gonadotropins. Corpora lutea have a species-specific life span, which is extended in viviparous squamates.

Endocrine Regulation of Reproductive Behavior

Studies of endocrine control of reproductive behaviors in amphibians and reptiles focus on two areas (see [Woodley \(2011\)](#), [Johnson and Wade \(2011\)](#), [Sinervo and Miles \(2011\)](#), and [Martín and López \(2011\)](#)). The first area involves courtship and mating behaviors. In amphibians and reptiles, auditory, visual and/or chemosensory (pheromonal) cues are important in courtship and mating, although reptiles mostly utilize visual and/or chemosensory cues.

The second area involves parental behavior. Although many species lay their eggs and never look back, some exhibit elaborate behaviors to protect their eggs and/or young and enhance their survival.

Reproductive Behavior of Amphibians

Reproductive behavior in amphibians involves a number of hormones in addition to those of the HPG axis. These include prolactin, AVT, and corticosterone. Pheromones have been identified in urodele reproduction, but anurans seem to rely more on visual, auditory, and tactile clues. Parental behavior has been described only in anurans.

Fertilization is external in most anurans but internal in urodeles and gymnophionids. Cloacal glands stimulated by androgens and prolactin are responsible for secretion of spermatophores in urodeles that are used in sperm transfer to the female. Gymnophionids employ a copulatory organ (phallodeum) for sperm transfer. Sperm may be stored in females in special structures called spermathecae associated with the oviducts, and the eggs may be fertilized at a later time.

Migratory behavior

Prior to breeding, some terrestrial amphibians migrate to aquatic breeding sites. This “water drive” behavior is triggered by prolactin. Endocrine control is not understood for desert spadefoot toads living in underground burrows that respond to the sound of heavy rains as a signal to leave their burrows and seek temporary ponds in which to lay their eggs.

Advertising

Once anurans reach the breeding site, males typically produce calls that attract reproductive females. Androgens appear to be responsible for development of the calling apparatus in males as well as the intensity of calling. Calling also is influenced by AVT although that role may vary by species. Additionally, plasma corticosterone levels are positively associated with calling in several species but negatively associated in others ([Carr, 2011](#); [Woodley, 2011](#)).

Clasping behavior (amplexus)

Male anurans characteristically grasp the back of a receptive female with the help of nuptial pads associated with forelimbs and release sperm as the female releases her eggs. This clasping behavior is termed amplexus and may trigger release of eggs from the female. Although androgens are responsible for secondary sex characteristics such as the nuptial pads, it is not clear what role androgens play in the initiation of amplexus. Administration of androgens can activate amplexus in male *Xenopus laevis* but are ineffective in *Rana pipiens*. A role for pheromones has yet to be demonstrated, but a peptide with female attracting properties has been isolated from the skin glands of one male anuran.

Amplexus in the newt, *Taricha granulosa*, is induced by AVT and antagonized by corticosterone. During amplexus, the male mounts from above and attempts to rub his chin on the female’s nasal region to transfer pheromones that will enhance his chances of spermatophore transfer. Pheromone roles are known for other urodeles as well.

Anuran parental behavior

Retention of eggs by females might be interpreted as prenatal care of young. Female marsupial frogs, for example, actively place fertilized eggs into an estrogen-dependent pouch that develops on their dorsal surface. Males of the midwife toad wrap the strings

of jelly containing the eggs around their legs and periodically return them to the water to moisten them and eventually to allow the hatching tadpoles access to water. Males of the terrestrial glass frogs of Central America carry moisture to their eggs that develop on land. They also protect the otherwise exposed developing young from predatory spiders until they hatch as miniature glass frogs. Other frog species produce elaborate foam nests where the young develop. The endocrine control of these behaviors has not been examined.

Reproductive Behaviors of Reptiles

At the onset of breeding, testosterone rises in male reptiles and is considered to be a key regulator of male reproductive behaviors. In many reptilian species, dominant males actively defend territories that contain females with whom they can mate. Defensive behaviors include aggressive attacks such as chasing and biting rival males, as well as dominance displays like head bobbing and push-ups as exhibited by many male lizards. Males lacking territories may still have mating opportunities; non-dominant “sneaker” males adopt the strategy of briefly entering a dominant male’s territory and copulating with females. Dominant males generally have higher androgen levels than their non-dominant conspecifics. Testosterone is also associated with the expression of male courtship behaviors in most species. Limited evidence demonstrating the presence of aromatase in the reptilian male brain suggests that testosterone may be converted to estradiol before stimulating male sexual behaviors.

The sexual behaviors of female reptiles may be influenced by estrogens, testosterone and/or progesterone. Mating usually takes place when estrogens released by the ovaries reaches a peak, and exogenous estradiol can activate receptive behaviors in females whose ovaries have been removed. Testosterone also is elevated in many female reptiles during courtship and mating, and may increase female receptivity. In the all-female lizard *Cnemidophorus uniparens* that reproduces by parthenogenesis, individuals engage in both male and female pseudosexual behaviors: before ovulation, they exhibit female-like receptive behaviors under the influence of high estradiol levels, and after ovulation, when progesterone levels are high, the behavior switches to male-like mounting (Fig. 7).

Pheromones secreted by cloacal glands of male and female reptiles also play important roles in reproductive behaviors. Pheromones can modulate male social dominance hierarchies, female mate choice, and mating behaviors (Martín and López, 2011). Stressors or corticosterone treatment inhibit male territorial, courtship and mating behaviors in some species, but female reproductive behaviors appear to be relatively unaffected by stress (Tokarz and Summers, 2011).

Although most reptiles abandon their eggs after oviposition or their young at birth, some species exhibit behaviors that increase the odds of survival of their young. These behaviors include nest site selection, nest-building, nest guarding and direct care of the

Fig. 7 Comparison of mating behavior in unisexual and bisexual lizards. Female-like and male-like behavior in the all female whiptail lizard (*Cnemidophorus uniparens*) is compared with female receptive behavior in a bisexual lizard, the little striped whiptail (*C. inornatus*). The differences in estradiol levels for the two species are illustrated (red lines). Female-like behavior in *C. uniparens* is elicited by a lower estrogen level and is followed by male-like copulatory behavior. The circles represent size of the ovarian follicles and the ovals indicate presence of eggs in the oviduct. Reprinted with permission from Norris, D.O., Carr, J.A., 2013. Vertebrate Endocrinology, fifth ed. San Diego, CA: Academic Press (Elsevier).

young, the latter observed in crocodilians. For example, female American alligators collect nesting materials to carefully create and shape their nests. While the eggs are incubating, females defend the nests against predators. The young begin to call even before hatching, and the female responds by excavating the terrestrial nest. She then carries the hatchlings in her mouth to the water. Males may also participate in care of the young to a lesser extent. The endocrine control of these parental behaviors is not well understood, but the possibility that prolactin may activate parental care in crocodilians as seen in other vertebrates is intriguing.

Glossary

AKH, or Adipokinetic hormone Peptide family, mainly produced and released from the glandular Corpora Cardiaca (CC), known regulators of the insect energy metabolism.

Corpora allata CA are the main Juvenile hormone synthesizing glands and part of the retrocerebral complex, present in both larvae and adults.

Dsx Doublesex gene a gender executer displaying a male and female specific splice variant.

E and 20-E, Ecdysteroids The typical insect steroids synthesized from dietary cholesterol. In larvae they initiate ecdysis. In adults the synthesized ecdysone mainly of gonad origin is enzymatically activated into 20-OH-ecdysone.

EcdR, Ecdysteroid receptor A cytoplasmic receptor family that, following ligand binding, heterodimerizes with a retinoid X co-receptor as ultraspiracle, and binds ecdysteroid responsive elements of target genes.

Fat body Metabolic center and energy storing organ.

Fruitless A gender executer gene displaying gender specific splice variants mainly regulating male accessory functioning, mating behavior and gender specific partner attraction via fruitless expressing neuronal plasticity.

Gynandromorph Insect with half the body cells displaying male phenotype and the other half displaying female phenotype. They result from X chromosome loss early in embryonic development in combination with the recessive X chromosome gender determination principle in insects.

ILP, insulin like hormones Neuropeptides involved in sensing and communicating the insects energy status. Some members are known ecdysiotropins. Insulin peptides regulate gene expression by sequestering FOXO, a known inhibiting transcription factor, from the nucleus.

JH, Juvenile hormones Sesquiterpenoid hormones mainly produced in CA but also released from male accessory glands. Most insects use JH III as functional hormone.

Met, methoprene tolerant receptor Binds JH, heterodimerizes with a steroid receptor type co-activator, as Taiman, prior to exerting transcription-regulating activity.

OEH Ovary ecdysteroidogenic hormone of mosquitoes, one of the few identified brain derived gonadotropins of insects displaying ecdysiotropic activity.

OMP Ovary maturing parsins of locusts, being ecdysiotropic.

Ovulin A male derived sperma peptide having receptors in the female oviducts.

Sex peptide A male derived sperm peptide affecting female reproduction.

TMOF Trypsin Modulating Oöstatic factor, an ovary derived factor that in the midgut translationally regulates Trypsin activity.

TOR Target of rapamycin, a cellular kinase pathway.

Vitellogenin Female specific yolk precursor protein, produced in the fat body and sequestered and accumulated as vitelline by the developing egg follicles.

YP Yolk polypeptides, dipteran female specific fat body derived yolk precursor polypeptides.

Introduction

The high reproductive capacity of insects, in combination with a terrestrial lifestyle of many species, represents a key element in explaining their evolutionary success and diversity. Insects reproduce sexually, a trait that most probably evolved in an attempt to cope with invading pathogens (De Loof *et al.*, 2016). Sexuality includes the integrated process of germ cell line formation, gonad differentiation, gametogenesis, yolk formation, partner attraction, courtship, copulation and deposition of fertilized chorionated, evaporation-resistant, eggs. Post-embryonic larval growth of insects is punctuated by molts, during which the animal produces a new skeleton (Krüger *et al.*, 2015). To acquire the necessary morphological and physiological characteristics for reproduction in the adult stage, insects undergo metamorphosis. Nymphs of hemimetabolous insects gradually acquire their adult phenotype. Internally, gonads develop and gametogenesis becomes apparent, starting in the second or third larval stage, as does the appearance of external sex-specific genitalia. Holometabolous larvae do not resemble the adult phenotype and, although gonadal imaginal discs develop, this is not yet visible in the differentiation of their external genitalia. However, the larval or pupal cuticle of holometabolous

[☆] A tribute to Arnold De Loof, Insect Physiologist and Visionary.

insects can display either obvious or rather hidden sex-specific landmarks that allow gender determination. In contrast to spermatogenesis, being complete in most male insects at the start of their adult lifespan, many males display a lag period in their sexual maturation. This puberty process usually includes functionalization of the accessory glands and changes in behavior. Reaching sexual maturity can manifest itself externally, for example, by the cuticular yellowing in sexually mature male *Locusta migratoria* (Fig. 1). Whereas in Saturniid moths, the ovaries already develop to full maturity during metamorphosis, in most other species the ovarian follicles are still yolkless at the onset of the adult stage, necessitating a complex process of hormonally controlled vitellogenesis.

Sexual Differentiation: Combined Cell Autonomous and Hormonal Events. A Role for Sex Hormones in Insects

In most insects, as in other sexually reproducing organisms, gonadal sex (testis producing spermatozoa and ovaries producing eggs) is determined at fertilization, the moment of conception. This primary sex strictly depends upon the genotype of zygote-derived germ cells. In many insects, for example, in the fruit fly, *Drosophila melanogaster*, although having X and Y heteromorphic sex chromosomes, sex- and gender determination merely depends upon the ratio X chromosomes: autosomes, making XX: AA individuals female and both XY: AA and XO: AA males. Many other insects even do not have a morphological distinguishable Y chromosome, and sex is determined in XX: AA and XO: AA fashion. In Lepidoptera, like the silk moth *Bombyx mori*, as in birds, females represent the heterogametic sex (ZW), while males are homogametic (ZZ). Many insects, including social insects like bees and wasps, experience haploid-diploid sex determination. This means that females always derive from fertilized eggs whereas parthenogenetic development of unfertilized eggs gives rise to haploid males. Regarding the molecular mechanism of these seemingly different ways of sex determination, the generally accepted idea is that, governed by a cascade of differential transcriptional activation and inactivation steps, a female- and male splice variant of the gender executer gene, *doublesex* (*dsx*) is generated. Anyway, *primary sex differentiation* is said to be strictly genetic. Importantly, many scientists believe that also setting the *gender phenotype* in somatic cells of insects can only be strictly genetic, and has to follow the same principles as explained for gonadal differentiation. Such reasoning is in firm contrast to the established mechanism in vertebrates, in which upon differentiation, the primary gonads start secreting steroid sex hormones testosterone and 17 β -oestradiol that govern the development of the somatic- and behavioral sexual phenotype. The usual argumentation, supposed to confirm the “insects have no sex-hormones” hypothesis, is based upon the existence of insect gynandromorphs. One half of such individual has genotypic male cells (XO: AA) displaying the male phenotype, whereas in the other half the genotypic female cells (XX: AA) have female phenotype. Because both cell types are exposed to an identical hormonal blend of both ovary- and testis-derived hormones, it is thought that a role for sex hormones should be excluded. However, in some bird species, for example, chicken and zebra finch, comparable sexual gynandromorphs occur, though no one questions the existence of sex hormones in birds (review Clinton *et al.* (2012)). Thus, in insects too there should be a way out of the dilemma. Indeed, it is often overlooked that, as the result of developmental differentiation, both sides of a gynandromorph insect can have different receptors for the same hormones or that they do not as efficiently translate the hormonal input into downstream signals. That would explain why the same hormones can act differentially in different parts of the body. As will be further documented in this summary, genetic suppression of vitellogenin or yolk protein synthesis in previtellogenic female mosquitoes, is due to orphanizing the ecdysteroid receptor (EcdR). The mechanism involved is the selective recruitment of its intracellular USP binding partner toward an AHR38 receptor (Zhu *et al.*, 2000; Marquardt, 2005). Such mechanism may as well apply to male cells of the gynandromorph. Our reasoning gets extra support from experimental data obtained in *Drosophila* (Parisi *et al.*, 2010). They studied germ-line dependent gene expression in non-gonadal somatic tissues. They observed both germline-independent, cell-autonomous, sex-specific gene expression in germline-naïve animals, as well as germline-dependent gender-specific gene expression in germline-conditioned animals. These authors further observed the occurrence of a female-biased and

germline-dependent ecdysteroid titer, thereby confirming the existence of a hormonal axis between gonads and non-gonadal soma. Based upon research in female dipterans such as mosquitoes, fleshflies, fruitflies and houseflies, the importance of an ovary-fat body ecdysteroid axis indeed had long been evidenced. In Diptera, ecdysteroids are important for the female-specific stimulation of vitellogenin expression, a yolk protein precursor. Because injection of minute amounts of 20-OH ecdysone in adult male fleshflies induced the synthesis of yolk polypeptides by the fat body (Huybrechts and De Loof, 1977), these authors launched the idea that 20-OH ecdysone might very well be the female sex hormone of dipterans, and perhaps of all insects. They compared this induction of vitellogenin in male fleshflies with its counterpart in vertebrates, namely the induction of vitellogenins in the liver of roosters by injection of estrogens (De Loof and Huybrechts, 1998). Importantly, this hormonal overruling of repression of yolk protein synthesis in males was confirmed in *Drosophila*, in which gender executor DSX-responsive elements have later been identified within the promoter region of two of the yolk polypeptide encoding genes (Burtis *et al.*, 1991). Thus, combined action of cell-autonomous and hormonal steering is possible. In male *Bombyx mori* pupae, both ovary transplantation and injection of the vertebrate female sex steroid 17-beta estradiol stimulate the male fat body to synthesize vitellogenin. However, the situation in (some) Diptera and in the silk moth is not representative for all insects. Indeed, in the cockroach *Diploptera punctata* and in orthopterans as locusts the hormone that can overrule the genetic sex-specific expression turned out to be Juvenile Hormone, the other morphogenic hormone of insects (Mundall *et al.*, 1979; Hult *et al.*, 2015; Wang *et al.*, 2017). In the next paragraphs, we will elaborate on the role of either hormone in regulating reproduction-related activities in insects.

Re-use of Existing Hormonal Pathways in Regulating Female Reproduction

The silverfish *Lepisma saccharina*, and firebrat *Termobia domestica*, both members of the phylogenetically old, wingless insects display throughout their extended lifespan continued cycles of ecdysis, punctuated with cycles of vitellogenesis and egg deposition. The co-regulation of both cyclic processes suggests a role for the two classic developmental hormones, Juvenile Hormone (JH) and ecdysteroids in regulating both molting and reproduction. Combined, quantification of hormone titers and surgical removal or inactivation of endocrine glands indicated that vitellogenin synthesis in the firebrat happens under a condition of elevated JH and lowered ecdysteroids titers. In silk moths, both vitellogenin synthesis, starting in the cocoon spinning larvae, and yolk deposition occur under conditions allowing pupal-adult development. These implicate a lowered Juvenile Hormone titer in the haemolymph and elevated ecdysteroid concentrations (Swevers and Iatrou, 2003; Postlethwait and Giorgi, 1985). Combined, the apterygote and silk moth examples indicate the need for a correct balance regarding the concentration of both metamorphic hormones.

Juvenile Hormone and 20-OH-Ecdysone Acting in Concert

In almost all insects, copulation, fertilization and egg laying are restricted to the adult life phase, starting after the final molt in hemimetaboles, or after eclosion of the adult in holometaboles. These adults indeed continue to produce JH and ecdysteroids, both hormones that in the pre-adult stages are so important to drive developmental growth and metamorphosis. The corpora allata (CA), as part of the retrocerebral complex, continue to be the major site for synthesis of Juvenile Hormone, which, in most species, is JH III. Gonads and male accessory glands can be additional sources of active JH synthesis in the adult (Paroulek and Sláma, 2014). Only recently, the Methoprene-tolerant gene, Met, has been identified in different insects as an intracellular Juvenile Hormone receptor (Charles *et al.*, 2011). JH binding to its Met-receptor induces heterodimerization with a known steroid co-activator, Taiman, and this complex in the nucleus interacts directly with JH-responsive genes such as the *Locusta* vitellogenin gene (Wang *et al.*, 2017). Whether Met represents the only functional JH receptor is not known. De Loof *et al.* (2014) suggested that a sarcoplasmic reticulum SERCA-calcium pump harbors a binding pocket for sesquiterpenoids like JH that would activate the pump. In contrast to the CA, in most insects, but not in all, the prothoracic gland, the best documented larval site of ecdysteroid synthesis degenerates in adults. Nevertheless, all adult insects possess the ecdysteroid synthesizing Halloween genes and effectively synthesize ecdysteroids in their ovaries, testes and male accessory glands (see review by Lenaerts *et al.* (2016)). Noteworthy, ecdysteroids are usually synthesized and released as ecdysone, which later on can be converted into 20-OH ecdysone by peripheral organs such as Malpighian tubules. Ecdysteroids bind to their cognate cytoplasmic receptor, which, following heterodimerization with a retinoic acid or RXR-type receptor as Ultraspiracle, translocate to the nucleus. In the nucleus the complex, now being a transcription factor, interacts with ERE or ecdysteroid responsive elements that are present in the promoter region of target genes. In addition, a GPCR-type dopamine-ecdysteroid receptor (DopECR) has been described which regulates the non-canonical action of 20E affecting behavior, such as courtship, via CAMP signaling and neural plasticity (Abrieux *et al.*, 2013).

The extensive bibliographic data on the hormonal regulation of reproduction in insects, summarized in excellent reviews, report on results obtained in only a few dozen species, whereas the number of described insect species, in the United States alone, reaches over 100,000 as compared to the estimated number of some 30 million worldwide. Not every model insects turned out to be suitable for testing the effect of both JH and ecdysteroids. In the majority of models, the priming role of Juvenile hormone in making both fat body and ovaries competent to respond to additional hormonal instructions is generally accepted. Regarding vitellogenin synthesis, a select group of insects, including many orthopterans, cockroaches, coleopterans and hymenopterans was believed to function under JH dominancy (Group 1 insects according to Postlethwait and Giorgi (1985), Tufail *et al.* (2014), Tufail and Takeda, (2009)). In some of those species, for example, in *Leucophaea maderae* either no role for ecdysteroids (Don-Wheeler and Engelmann,

1997) or alternatively a repressor role for ecdysteroids was reported (Weaver *et al.*, 1984). Only in a few exceptions, aside the main role of JH, a stimulating role for ecdysteroids was evidenced or suggested for members of this group. The action of Ovary Maturing Parsin (OMP) upon vitellogenin synthesis in *Locusta migratoria* which, at least partially, might involve ecdysteroids represents a good example (Girardie *et al.*, 1998). In contrast to this mainstream, other insects are categorized as performing under ecdysteroid dominance. In the latter group, the Hagedorn model (Hagedorn, 1983) dedicated a primary role to the ovaries as major source of ecdysteroids, which in turn instruct the fat body to synthesize and secrete vitellogenin for uptake by the developing egg follicles (Group 2 insects according to Postlethwait and Giorgi (1985)). As in higher Diptera, yolk polypeptide synthesis by the fat body, in response to ecdysteroid stimulation, can occur independently of the presence of the ovaries in insects of Group 3. They have an additional, non-ovarian, site of ecdysteroid synthesis (Postlethwait and Handler, 1978; Huybrechts and De Loof, 1981).

Molecular Tools Evidence the Cross Talk Between JH- and Ecdysteroid-Signaling Pathways for Regulating Reproduction in Insects

In recent years, thanks to ever improving possibilities offered by the “molecular toolbox”, the role of JH and ecdysteroids became better understood in a few species by studying the expression and manipulation of enzymes and proteins involved in their synthesis, receptor signaling or metabolism. Data were collected under different physiological conditions and many times validated by quantification of their downstream gene products. In the cockroach, *Diploptera punctata*, gene profiling of EcdR and RXR/USP evidenced high ecdysteroid receptor expression not only in the ovary, but as well in nervous tissue and in the corpora allata. The combined RNAi knockdown of RXR/USP and EcdR, starting the first day of adult female development, demonstrated that ecdysteroids in this species come into action only toward the end of the vitellogenic cycle. At this particular moment, ecdysteroids initiate chorion gene expression. By their direct signaling at the level of the CA, they are assumed to negatively regulate JH, which is now no longer needed for vitellogenin synthesis (Hult *et al.*, 2015). In the hemipteran firebug, *Pyrrhocoris apterus*, allatotectomy abolishes egg development under reproduction-promoting long-day conditions. RNAi knockdown of either Met or its binding factor Taiman (Tai) both blocked vitellogenin synthesis in females. However, RNAi of Tai applied to last larval instars, blocked adult ecdysis as expected, but failed to introduce adult characteristics. In contrast, last instar adultoids, resulting from a similar RNAi using dsMet RNA, do display adult characteristics. As Tai represents also a known co-activator of EcdR, the question emerges to what extent the ecdysteroid pathway is affected by, or is affecting the clear-cut JH response in this species (Smykal *et al.*, 2013). Also in the locust *Schistocerca gregaria*, combined knockdown of both ecdysteroid receptors and their RXR heterodimer resulted in some surviving L5 instars that, although being unable to complete the final adult molt, already started vitellogenin synthesis. These data point toward a self-regulating feedback loop. Indeed, in the knockdown males an increase in total ecdysteroid titer was measured although the 20-E titer was not elevated. The observed start of vitellogenin uptake in the knockdown females further suggests a feedback interaction between the ecdysteroid- and the JH pathway. JH is believed to be indispensable for yolk accumulation by the developing follicles in insects, but authors did not yet challenge this possibility (Lenaerts *et al.*, 2016). Direct cross-talk between 20E and JH most probably also occurs via reciprocal interaction at the level of the EcdR and Met co-activators (Jindra *et al.* (2013) and cited refs) or via transcriptional interaction at the level of their effector genes (Jones *et al.*, 2011).

Feeding-Regulated Reproduction: AAs-TOR and Insulin as Main Mediators

In order to guarantee the production and deposition of chorionated, yolky eggs correct feeding conditions are required. Starvation usually inhibits or abolishes the progression of vitellogenesis. Hitherto, nutritional regulation of reproduction occurs in all insects (see review by Smykal and Raikhel (2015)). First, correct sensing of the nutritional status is essential, because without the necessary resources no yolky eggs can be produced. This nutritional sensing is of outermost importance for anautogenous species as blood-sucking mosquitoes and flesh flies, which need a protein meal to initiate vitellogenin synthesis. Amino acids sensing (AAs), mediated via the serine/threonine kinase TOR pathway represents the start for nutritional signaling along a parallel Insulin nutritional sensing and signaling mechanism (Badisco *et al.*, 2013). The increase in amino acids following digestion activates TOR that in turn activates S6K, and that inactivates 4EBP, allowing the GATA transcription factor being translated for transcriptional activation of vitellogenin synthesis. The conserved Insulin-signaling pathway starts by binding of Insulin-like peptides (ILPs), released upon feeding, to a tyrosine kinase transmembrane insulin receptor. It ultimately results in phosphorylation of FOXO and its sequestration from the nucleus allowing vitellogenin synthesis. Crosstalk between the insulin and AAs-TOR pathway exists via its main effector Akt/protein kinase B, a known suppressor of the negative regulators of TOR. Both TOR and Insulin-like peptides further connect the nutritional status to JH synthesis, which in JH-dominant insects is needed for vitellogenin synthesis and in ecdysteroid dominant insects it assures reproductive competence. In the latter, the importance of insulin-like peptides (ILPs) in the regulation of ovarian ecdysteroidogenesis is well documented (reviewed by Nässel and Vanden Broeck (2016)). In mosquitoes, blood feeding triggers both the release of brain-derived ILPs and ovary ecdysteroidogenic hormone (OEH). OEH binds to an ovarian receptor tyrosine kinase, and activates in this way protein kinase B/Akt of the insulin pathway in an insulin receptor-independent manner. This explains why either OEH or ILP3, in the presence of essential amino acids, can independently stimulate synthesis and release of ecdysteroids from mosquito ovaries to instruct the fat body for vitellogenin synthesis. Noteworthy, in insects as *Drosophila* and flesh flies, the follicle cells themselves produce yolk polypeptides under direct control of insulin, and independently of juvenile hormone

and ecdysteroids as well. All these data evidence a plethora of transactivation factors that converge at the level of the vitellogenin gene(s), which harbor(s) their cognate response elements in its promoter region.

Digestion itself is hormonally controlled. In cockroaches CCAP peptide and short neuropeptide-F (SNPF) both originating from neuro-endocrine cells and intestinal paraneurons, antagonistically regulate digestive activity. SNPF is a down regulator and CCAP is an up regulator (Mikani *et al.*, 2015). Also adipokinetic hormones (AKH), peptides known to be primarily involved in energy homeostasis and to act primarily on the fat body (Lorenz and Gäde, 2009), stimulate digestion in the firefly, *Pyrrhocoris apterus*, the cockroach, *Periplaneta americana* and the fleshfly, *Sarcophaga crassipalpis* (Bodláková *et al.*, 2016; Bil *et al.*, 2014). In the fleshfly, AKH receptor profiling attributed a switching function to AKH as it might favor the use of amino acids generated by digestion for vitellogenin synthesis in fed animals (Bil *et al.*, 2016). Noteworthy, the AKH receptor belongs to the GnRH receptor family. Finally, in *Drosophila*, the intestinal expression of allatostatin-A arrests food intake and digestion. It brings the fly in a post feeding energy-saving modus, again allowing the preferential use of digestion-derived amino acids (Chen *et al.*, 2016).

Brain Derived Gonadotropins and Gonadotropin Release Regulators

In contrast to the situation in vertebrates, the insect literature is confusing regarding the question which hormones are genuine gonadotropins, gonadotropin-releasing hormones, and sex hormones (=the gonadal executors). Both JH and ecdysteroids have often been described as gonadotropic hormones, erroneously in my opinion. Ecdysteroids, in the adult being mainly hormones synthesized by the gonads, are executors rather than gonadotropins. Accordingly ecdysteroids might better be named gonadal- or sex hormones as suggested earlier. Prothoracicotropic Hormone (PTTH), the ecdysiotropin that is synthesized by the brain, and that stimulates ecdysone synthesis in larval prothoracic glands has also been found in adults. Via interaction with its cognate receptor Torso, PTTH regulates ecdysteroid synthesis in male accessory glands (De Loof *et al.*, 2015). In adult female mosquitoes and in adult *Locusta migratoria* as well, ovary ecdysteroidogenic hormone (OEH) and ovary maturing parsin (OMP) respectively are identified gonadotropic ecdysiotropins. In other insect species, no such gonadotropins have been identified. Yet, their presence has been experimentally suggested in the fleshfly *Sarcophaga crassipalpis* (Bil and Huybrechts, 2016). The recent identification of the OEH hormone receptor in *Aedes aegypti* (Vogel *et al.*, 2015) might enhance the chances for identifying other members of this gonadotropin family in other species. This could be done via reverse pharmacology approaches, if the degree of structural conservation is substantial. Compared to ecdysteroids, the role of JH in adults is more complex. On one hand, JH produced by the CA is needed for the development of the ovaries and the male accessory glands (MAGs); thus, it functions as a true gonadotropin. Indeed, in many species allatectomy results in ovarian and MAG degeneration. On the other hand, in many insects it is as essential as ecdysteroids for control of the expression of the vitellogenin gene(s). Its binding to the Met JH receptor, upon heterodimerization, directly targets the vitellogenin gene expression, as does the ligand-activated EcdR-USp complex in some other insects. Brain-derived allatotropin (AT) and allatostatin (AST) neuropeptides, via their cognate receptors regulate JH synthesis by the CA in some species. By doing so, they function as genuine gonadotropins (see review by Verlinden *et al.* (2015)). However, from the literature, and especially from the tissue distribution profile of their receptors it is clear that the role of both AT and ATS is mainly situated beyond the brain-CA- ovary/fat body axis. This is illustrated by the antagonistic action of both ATs and ASTs on muscle contraction in the oviducts. Of the three types of identified allatostatins (Coast and Schooley, 2011) allatostatins B, or MIP-type allatostatins, are known prothoracicostatic peptides, but their role in downregulating adult ecdysteroid production remains to be clarified. In addition, Sex Peptide (see below) shares evolutionary relationship with B-type allatostatins, which are believed to be the ancestral ligands of its receptor. Allotostatins C, or PISCF AST, are also functionally pleiotropic. They have receptors on the reproductive organs. In addition to these ecdysteroids- and JH-regulating neural factors, numerous other neuropeptides exemplified by Nalasin, SIFamide and Corazonin affect reproduction and copulation-related behavior (Schoofs *et al.*, 2017). Finally, in the context of gonadotropins and anti-gonadotropins also the role of oostatic peptides produced by the ovaries themselves such as Ae-TMOF and Neb-TMOF downplay the synthesis of vitellogenins in the fat body. They act via translational inhibition of trypsin-type digestive enzymes (Hlaváček, 2013).

Mating Enables Males to Affect the Endocrine Regulation of the Female Reproduction Process

With the exception of facultative- or obligate parthenogenetic females, virgin females of most species, although completing oogenesis and vitellogenesis in some follicles, usually deposit a lesser number of eggs than mated ones. Their egg laying occurs less organized as well. Apart from the behavioral impact of mating, in many species the males transfer potent endocrine regulators to the females. The male accessory glands (MAGs) of *Anopheles gambiae* turned out to be major sites of 20E synthesis. Moreover, in this malaria-vectoring mosquito 20E is transferred during mating to the female in which this allohormone is suggested to prime vitellogenesis the same way as the endogenous female sex steroid 20E does (Pondeville *et al.*, 2008). Such mating-derived priming, if widely occurring, would explain the earlier mentioned initiation of yolk polypeptide synthesis in ovariectomized female flies. The *Anopheles* scenario may be an exception. Indeed, in most other dipterans adult males hardly produce any ecdysteroids except for the local synthesis in the testes were they even install local YP synthesis (Majewska *et al.*, 2014). The 20E titer is low in male insects, at least when compared to the values in females. A second hormone that may be transferred into females is JH. In some species, for example, in *H. cecropia*, MAGs synthesize and store substantial amounts of Juvenile hormone. Apart from these examples, it is

generally accepted that specific proteinaceous ejaculate components fulfill endocrine functions. This is important for assuring male evolutionary fitness. This can be achieved by, for example, reducing female receptiveness to other males, or by installing a copulation plug, or by directly stimulating oogenesis and egg deposition. In *Drosophila*, Sex peptide, a MAGs-derived peptide directly influences the neuroendocrine regulatory pathway in the female; it elicits both physiological and behavioral changes (Liu and Kubli, 2003). The seminal protein Ovulin mediates ovulation by interacting with the female octopamine-signaling pathway (Rubinstein and Wolfner, 2013). So far, both MAG-derived peptides, Sex peptide and Ovulin, have no proven orthologs in species outside the *Drosophila* genus, although several Mag components exert similar functions in most studied species.

Heterosexual and Homosexual Courtship Behavior in Males

Following stimulation by female sex pheromones, male flies start typical courtship behavior including chasing, singing and mounting. Accordingly, as does *dsx*, the *fruitless* gene and its sex-specific spliced transcript are considered executors of sexual differentiation in somatic cells, including behavior-regulating neurons. *Fruitless* gene mutant males obviously changed sexual preference as they started chaining with male flies when reared in co-habitation. Accordingly, changed sexual preference became a hallmark of *fruitless* mutants, as it was believed to install a male-directed neural circuitry in neurons expressing the mutant *fruitless* gene. In their recent review, Yamamoto and Kohatsu (2016) question this paradigm as they report that sexual preference in the *fruitless* mutants seems to be plastic. It has rather to be seen as an activity-induced or experience-dependent trait, installed by the experimental male group rearing. Indeed, male *fruitless* mutants that during the experiment have only contact with females will display some degree of chaining with their female partners, even if they do not belong to the same species. Complementing the experiments in fruitflies, which suggest an epigenetic interaction of *Fruitless* in the brain, in locusts, *fruitless* knockdown by RNAi indicates a direct involvement in male copulation behavior and fertility, the latter possibly due to an altered transfer of seminal fluid (Boerjan et al., 2011, 2012).

Endogenous Encoded miRNA, an Additional Level of Regulation

In conclusion, this summary on the combined cell-specific and hormonal regulation of reproduction in insects focuses more upon the role of hormones in females than in males. Fig. 2 summarizes the main actors in this process. It can be expected

Fig. 2 Both feeding and copulation are important regulators of reproduction in insects. Insulin signaling, amino acid sensing and copulation derived factors, as Sex Peptide, communicate the energetic or mating status to the brain and initiate the reproduction process in the female. Brain derived gonadotrophins, mainly ecdysteroidogenic in nature instruct the ovaries. Allatotrophins and allatostatins control CA activity. In a species dependent fashion, Corpora allata derived JH or ovarian ecdysteroids in concert and mainly antagonistically regulate vitellogenin synthesis by the fat body. Within fat body cells multitudes of signals converge and turn the regulation of vitellogenin gene functioning into a complex process. 20E, 20 hydroxyecdysone; AAs, amino acids sensing; AKH, adipokinetic hormone; CA, corpora allata; CC, corpora cardiaca; EcdR, ecdysteroid receptor; ILP, insulin like peptide; JH, juvenile hormone; Met, methoprene tolerant JH receptor; OEH, ovary ecdysteroidogenic hormone; OMP, Ovary maturing parsin; sNPF, short neuropeptide F; TOR, target of rapamycin.

that in the near future small RNAs, which are encoded in the genome, will manifest themselves as an additional level of regulation of reproduction. Apparently, such small RNAs act via their intrinsic posttranscriptional gene-knockdown capacities (Wynant *et al.*, 2015).

Endocrine Control of Crustacean Reproduction

In oviparous animal except for mammals, vitellogenesis as a process of yolk formation is a crucial event in oogenesis, which is essential to normally advance embryonic and larval development. Crustaceans repeat molting to grow and their vitellogenesis undergoes between successive molt cycle. The repressive involvement of eyestalk in ovarian development of decapod crustaceans was demonstrated by eyestalk ablation first, which resulted in induction of ovarian maturation in the grass shrimp, *Leander serranus* (Panouse, 1943). Neurosecretory cells from the X-organ extend the axonal ends into the sinus gland and the X-organ-sinus gland (XOSG) is present in the eyestalk. The eyestalk ablation accelerates molting and maturation of ovary associated with secondary vitellogenesis, suggesting occurrence of hormones of molt and vitellogenesis inhibition in the XOSG distributed in eyestalk. Vitellogenesis-inhibiting hormone (VIH) was isolated from the XOSG and its primary structure was determined in American lobster, *Homarus americanus* (Soyez *et al.*, 1991). The VIH consisted of two isoforms and only one isoform showed the inhibiting effect on vitellogenesis. Around the same time, a family of multifunctional peptides was found from the XOSG in Mediterranean green crab, *Carcinus maenas*, which is called crustacean hyperglycemic hormone (CHH) peptides family (Keller, 1992). Sequence of CHH peptide was highly conserved among Crustacea and characterized by conservation of common structure to molt-inhibiting hormone (MIH) and VIH in the eyestalk, which are included in the same peptides family. The CHH regulated carbohydrate metabolism and somewhat inhibit vitellogenesis. MIH predominantly inhibited molting in the Mediterranean green crab, but MIH of blue crab, *Callinectes sapidus*, promoted vitellogenesis retaining molt-inhibiting activity (Zmora *et al.*, 2009). Mandibular organ-inhibiting hormone (MOIH) was also identified as a member of the CHH peptides family in the eyestalk, which has the inhibitory effect on vitellogenesis (Webster *et al.*, 2012). The VIH, CHH and MIH peptides regulate vitellogenesis directly from the XOSG, while the inhibitory function of MIH and MOIH on molting and vitellogenesis, respectively, are mediated through other organs. MIH inhibits synthesis of 20-hydroxyecdysone (20E) in the Y-organ and the 20E secreted from the Y-organ promotes both molting and vitellogenesis (Chang and Mykles, 2011). MOIH represses synthesis of farnesoic acid (FA) and methyl farnesoate (MF) in the mandibular organ and the FA and MF accelerate vitellogenesis associated with 20E (Mak *et al.*, 2005; Wainwright *et al.*, 1996; Fig. 1).

Fig. 1 Structural formula of 20-hydroxyecdysone (20E), farnesoic acid (FA) and methyl farnesoate (MF).

Fig. 2 A schematic diagram of hormonal control in crustacean vitellogenesis. CHH, crustacean hyperglycemic hormone; VIH, vitellogenesis-inhibiting hormone; MIH, molt-inhibiting hormone; MOIH, mandibular organ-inhibiting hormone; VSH, vitellogenesis-stimulating hormone; 20E, 20-hydroxyecdysone; MF, methyl farnesoate; FA, farnesoic acid.

The neurosecretory cells of brain and thoracic ganglia is known to secrete vitellogenesis-stimulating hormone (VSH) to promote ovarian maturation although the chemical nature is not adequately understood and its gonadotrophic function is only recognized by removal and implantation experiments (Yano, 1998). The vitellogenesis-stimulating neuropeptide, Mee-MIH-B, was found in the brain and thoracic ganglia in the shrimp, *Metapenaeus ensis*, and the Mee-MIH-B directly induced vitellogenin gene expression and increased vitellogenin protein in hemolymph retaining low molt-inhibiting activity (Tiu and Chan, 2007). Taken together, female maturation in crustaceans is under the control of the XOSG system directly or indirectly through Y-organ and mandibular organ, and also regulated by the brain and thoracic ganglia (Fig. 2). These peptides originated from the XOSG appeared to regulate spermatogenesis in decapods crustaceans like a function on female reproduction, but it is very little known (see Subramoniam (2017)).

Endocrine Control of Molluscan Reproduction

Bivalves

The mitotic division of gonial cells is a process to multiply germ cell at the early stage of gametogenesis in any kind of oviparous animals. Spermatogonia in bivalves is proposed to be classified into a spermatogonial stem cell and a series of development of differentiated spermatogonia during early spermatogenesis on the basis of proliferation potency of spermatogonia (Osada *et al.*, 2007). The central nervous system of bivalves generally consists of three ganglia; cerebral, pedal and visceral ganglia (Fig. 3). Mathieu *et al.* (1988) found occurrence of a neural factor named “gonial mitosis-stimulating factor” (GMSF) from the cerebral ganglion of the mussel *Mytilus edulis* first, which stimulated [³H] thymidine incorporation into dissociated germ cell suspensions of the mussel mantle tissue. Gonadotropin releasing hormone (GnRH) like factor found in the cerebral and pedal ganglia of scallop *Patinopecten yessoensis* stimulated mitosis of spermatogonia through receptor mechanism under a neuroendocrine control (Nakamura *et al.*, 2007). The GnRH superfamily, which includes GnRH, adipokinetic hormone (AKH), corazonin (Crz), and AKH/Crz-related peptides (ACP), is almost ubiquitous throughout the bilateral animals including molluscs (Roch *et al.*, 2011). Vertebrate GnRHs could also affect mitosis of germ cells in the mussel and the Pacific oyster and the GnRH-like neurons were identified in the central nervous system (CNS). And then two GnRH-like peptides were confirmed by mass spectrometry from the CNS in Pacific oyster and Japanese scallop, pQNYHFNSNGWQP-NH₂ (Cg-GnRH-a; amidated undecapeptide) and pQNYHFNSNGWQPG (Cg-GnRH-G; non-amidated doecapeptide) in Pacific oyster, and pQNFHYSNGWQP-NH₂ (py-GnRH11AA-NH₂) and pQNFHYSNGWQPG-OH (py-GnRH12AA-OH) in Japanese scallop (Bigot *et al.*, 2012; Nagasawa *et al.*, 2015a). The extra dipeptide insertion after N-terminal pyro-glutamate residue is recognized in both bivalve species in common with other molluscan species and characterized to be definitely different from vertebrate GnRHs. And then in vitro administration of the synthesized py-GnRH11AA-NH₂ induced spermatogonial proliferation in testis tissue of scallop mediated through estrogen whose synthesis could be induced by py-GnRH11AA-NH₂ (Osada and Treen, 2013). Interestingly, the synthetic py-GnRH11AA-NH₂ accelerated spermatogenesis associated with a significant increase in testis mass and conversely inhibited oocyte development associated with an apoptosis of oocyte and newly development of male germ cell, implying early phenotypic alteration to masculinization and GnRH involvement in sex differentiation in bivalve molluscs (Nagasawa *et al.*, 2015b).

Fig. 3 Schematic drawing of the distribution of the monoamine perikarya in the central nervous system of *Patinopecten yessoensis* (Ventral view). AG, accessory ganglia; AL/al, anterior lobe; CG, cerebral ganglia; CVC, cerebrovisceral connective; II, lateral lobe; PG, pedal ganglia; PL/pl, posterior lobe; VG, visceral ganglia; ▲, serotonin perikarya; □, catecholamine perikarya. Modified from Matsutani, T., Nomura, T., 1986. Serotonin-like immunoreactivity in the central nervous system and gonad of the scallop, *Patinopecten yessoensis*. *Cell Tissue Res.*, 244, 515-517.

Steroid production and function on mollusc reproduction is well examined using vertebrate steroids; quantification of steroids by immunological method and HPLC, etc., identification of putative sites of steroid production, and induction of sex reversal and oogenesis have been demonstrated (see Lafont and Mathieu (2007)). In the developing or growing stage of the ovary, the oocyte rapidly accumulates vitellin (Vn) as a major yolk protein in oocytes. Vitellogenin (Vtg), precursor protein of Vn, is synthesized in and provided from the follicle like cells to the oocytes in bivalves (Matsumoto *et al.*, 2003; Osada *et al.*, 2004). The Vn accumulation into oocyte of scallop and oyster was experimentally induced with vertebrate estradiol-17 β (E₂) and a neural factor named "vitellogenesis promoting factor (VPF)" in vitro (Osada *et al.*, 2003). The estrogen signal is generally transduced into cells by estrogen receptor (ER), a member of the nuclear receptor (NR) superfamily, in vertebrates to regulate hormone-dependent transcription of target genes, such as Vtg. The bivalve ER ortholog was isolated in Pacific oyster and mussel and dominantly expressed in the gonad (Matsumoto *et al.*, 2007; Nagasawa *et al.*, 2015c). A significant increase in Vtg mRNA expression was observed in mussels exposed with vertebrate E₂ during the early stage of gametogenesis (Ciocan *et al.*, 2010), implying mediation of ER, although the question of what roles mollusc ERs have remains unanswered.

Spawning in bivalve mollusc is suggested to correlate with an environmental fluctuation, e.g. temperature, lunar age, illumination, salinity, abundance of phytoplankton, food availability, physical shock, tidal surge, drying and radical oxygen as a stimulus. These environmental cues are received by the CNS and converted into release of serotonin (5-hydroxytryptamine, 5-HT) of neurotransmitter as a trigger for spawning from the CNS. The primary role of 5-HT on spawning is an induction of meiosis reinitiation of prophase-arrested oocytes, oocyte maturation, as evidences by germinal vesicle breakdown (GVBD), and initiation of sperm motility (Tanabe *et al.*, 2006; Alavi *et al.*, 2014). The 5-HT signal transduction into oocyte and sperm is mediated through 5-HT receptor on the membrane with Ca²⁺ influx for oocyte, K⁺ efflux and Ca²⁺ & Na⁺ influx for sperm (Tanabe *et al.*, 2010; Alavi *et al.*, 2014). The 5-HT function is modulated with prostaglandin F₂ α (PGF₂ α) and PGE₂, which play a role as a suppressive and acceleratory modulators of 5-HT-induced egg release, respectively (Matsutani and Nomura, 1987). Vertebrate steroids, estrogen and testosterone, which are detected in several bivalves, led to rising sensitivity to 5-HT involved in spawning (Osada *et al.*, 1992; Wang and Croll, 2006). Peptidic or proteinous modulators for 5-HT-induced oocyte maturation and spawning were also found in bivalves. *Spisula* factor and oocyte membrane component originating from oocyte inhibited 5-HT function in the Atlantic surf clam *Spisula solidissima*, and a novel neural factor to arrest 5-HT-induced oocyte maturation, named "oocyte maturation arresting factor," OMAF was found in the CNS of the scallop (Yuan *et al.*, 2012). Intriguingly, neutralization of endogenous OMAF with antibody strongly amplified the 5-HT-induced release of egg and sperm. Taken all together, 5-HT is an essential neurohormone for crucial

events of oocyte maturation and sperm motility and following spawning of bivalves. The mode of action of 5-HT on activation of germ cell and gonoduct is regulated by OMAF, steroids and PGs.

Gastropods

The neuroendocrine control of egg-laying has been studied convergently in two kinds of gastropods, sea hare *Aplysia californica* and pond snail *Lymnaea stagnalis*. Egg-laying of these species involves in a series of reproductive process, ovulation, packaging the fertilized eggs into the egg string/egg mass and oviposition like in other gastropods (Mukai and Morishita, 2016).

The *Aplysia* CNS consists of pair of five ganglia, buccal, cerebral, pleural, pedal and abdominal ganglia as shown in Fig. 4. The bag cell neurons consisting of around 400 cells, in which an egg-laying stimulating function was found, are located adjacent the abdominal ganglion (Fig. 4). In fact injection of a homogenate of the bag cells into mature *Aplysia* induced egg-laying (Kupfermann, 1970). Other egg-laying stimulatory factors were identified in the atrial gland of an accessory sex organ as an exocrine organ which is located on the reproductive tract, and secreted from the atrial gland into the freshly deposited egg strings of *Aplysia*, which promoted egg-laying in conspecifics as a pheromone (Nagle *et al.*, 1985; Rothman *et al.*, 1986). The neuropeptide, egg-laying hormone (ELH), is secreted by depolarization of the bag cells in a Ca^{2+} -dependent manner. The ELH preprohormone with 242 amino acid residues was defined, which is cleaved to generate mature ELH, α , β , γ , δ -BCPs (bag cell peptides), califin (small) and acidic peptide (Table 1). The ELH is thought to be released from the bag cell in the space between the surface of the abdominal gland and the overlying connective tissue sheath and delivered to the abdominal ganglion to regulate the neural activities for egg-laying behavior. And then the ELH directly induced the release of oocytes from the isolated piece of ovotestis, implying a direct action on a series of reproductive process to deposit egg strings. The auto-excitatory BCPs originated from the bag cells induce depolarization of the bag cell membrane itself binding to the autoreceptors of the bag cell, which may involve in secretion of ELH from the bag cells. Other two peptides, califin and peptide A, identified in the atrial gland have an *in vivo* effect on induction of egg-laying, whereas the atrial gland is exocrine organ to secrete both califin and peptide A into the reproductive tract where egg strings pass, not endocrine organ to be able to directly affect the ovotestis (Table 1). ELH, BCPs and other peptides from the bag cell and atrial gland govern discharges of egg strings in *Aplysia*, but not gonadal maturation.

The structure of *Lymnaea* CNS is well studied as well as *Aplysia* CNS. The caudodorsal cells (CDCs) consisting of 50–100 cells are distributed on the dorsal side of pair of cerebral ganglia in *Lymnaea* and are functionally equivalent neurosecretory cells to the bag cell in *Aplysia* (Fig. 5). It was first evidence of occurrence of egg-laying activity in CDCs that ablation of the CDCs in adult snail arrested egg-laying while injection of crude extract of CDCs revived egg-laying process (Geraerts, 1976). The 259-amino acid-long preprohormone identified in the *Lymnaea* CDCs includes caudodorsal cell hormone (CDCH-I), α , β_1 , β_2 , β_3 -CDCPs (caudodorsal cell peptide) and calfluxin (Vreugdenhil *et al.*, 1988). The CDCH-I with 36 amino acid residues plays a key role in ovulation and egg laying behavior. Subsequently another CDCH (CDCH-II) with 44 amino acid residues encoded by different gene from CDCH-I was identified (Li *et al.*, 1992; Table 1). CDCPs show similar auto-excitation of CDCs to the bag cells in *Aplysia* which respond to BCPs via autoreceptor. Neuropeptides from CDCs, CDCH and CDCPs etc, may involve in coordinating from ovulation through oviposition.

Cephalopods

In cephalopods, reproductive process is described as follows: for female vitellogenesis, egg laying, formation of protective egg coat by the oviduct gland and encapsulation of spawned egg mass by the nidamental gland, for male formation of spermatophore and ripening of reproductive tract. The involvement of CNS of cephalopods in hormonal control of reproduction was also expected as in other molluscan species (Fig. 6). Ablation and enlargement of the optic gland resulted in regression of testis and its duct, and enlargement of testis and its duct, respectively (Wells and Wells, 1972). In general gonad maturation of the cephalopods is controlled by photoperiod. Darkness activate development of gonad, whereas lightness inhibits the optic gland activity through activation of the subpedunculate lobe, implying that gonad maturation is regulated by the optic gland via the subpedunculate lobe receiving photoperiod signal through optic nerve. In addition to neural function, progesterone likely induces proliferation of follicle cell to synthesize yolk protein and results in vitellogenesis associated with the optic gland hormone (Di Cristo *et al.*, 2010). In the optic gland octopus GnRH (oct-GnRH) was identified, which is dodecapeptide with extra dipeptide insertion after N-terminal pyro-glutamate residue, pENYHFSNGWHPG-NH₂ (Iwakoshi *et al.*, 2002). The oct-GnRH neuron and nerve fiber distributed in the subpedunculate lobe and the posterior olfactory lobe, which innervate the optic gland (Iwakoshi-Ukena *et al.*, 2004). The oct-GnRH induces steroidogenesis of progesterone, testosterone and E₂ in the ovary where oct-GnRH receptor distributes (Kanda *et al.*, 2006). Oct-GnRH is suggested to be a key peptide in the subpedunculate/posterior olfactory lobes–optic gland–gonadal axis to control octopus reproduction.

Glossary

Circadian Clock A molecular machinery that functions on a 24 ± 4 h base (from the Greek *circa*: approximately, and *dian*: day).

Circannual Clock A molecular machinery that functions on a seasonal base.

Photoperiod Alternation of light (L) and darkness (D) during the 24 h cycle.

Introduction

In fish, reproduction displays cyclic variations at all levels of control: the seasonal information relayed to the circadian (biological) clocks, allows the production of rhythmic signals, which modulate the activity of the brain-pituitary-gonadal (BPG) axis, gonadal development and maturation, and finally courtship behavior and spawning (Cowan *et al.*, 2017; Falcón *et al.*, 2010a,b; Migaud *et al.*, 2010; Zohar *et al.*, 2010). Photoperiod, the main factor influencing the timing of fish reproduction, acts at different timescales from daily to once in a life (Juntti and Fernald, 2016). Photoperiod determines if daily or annual spawning occurs in the morning, afternoon or (most common situation) at night (Claydon *et al.*, 2014; Oliveira and Sánchez-Vázquez, 2010). In equatorial areas, it may occur throughout the year (Claydon *et al.*, 2014; Oliveira and Sánchez-Vázquez, 2010). Seasonal fish display a restricted spawning window, allowing partitioning between the energetic needs of reproduction and growth, and providing optimal conditions for offspring survival. Both functions are interconnected and rhythmic (Migaud *et al.*, 2010). Months of preparation precede, and a phase of arrest or recrudescence follows, the spawning window. Evidence for the presence of a circannual clock controlling fish reproduction has been obtained from studies in the trout (Duston and Bromage, 1991), catfish (Aggarwal *et al.*, 2014) and seabass (Prat *et al.*, 1999), which exhibit self-sustained circannual rhythms of spawning under constant conditions. The timing and duration of the spawning window is species-dependent (Oliveira and Sánchez-Vázquez, 2010). Spawning rhythms are synchronized by monsoons, tides and rainfalls in the tropics (Oliveira and Sánchez-Vázquez, 2010). An extreme situation is observed in some salmon and eel species that reproduce only once in their life before dying (Juntti and Fernald, 2016).

In brief, the control of reproduction is highly dependent on a precise timing provided by the circadian system.

The Circadian System

Organization of the Circadian System

The circadian system is made of central clocks, of organs that provide input to the clocks and others that receive rhythmic input from the clocks. This system, which provides information on daily and calendar time to the rest of the organism, allows predicting and anticipating the cyclic variations in the environment. A single system controls a myriad of events (Fig. 1) (Ekström and Meissl, 2010; Falcón *et al.*, 2010a,b). Under constant conditions, the central clocks oscillate in a free running mode (24 ± 4 h). The underlying molecular mechanism involves the interaction of transcriptional activators and repressors that create two interlocking feedback loops, and virtually all fish cells possess such a machinery (Whitmore, 2010). Thus, multiple cellular clocks are present, organized in a network of more or less potent oscillatory units (Fig. 1). The 24 h light/dark (L/D) cycle is the main synchronizer of the clocks' activity, but other factors (temperature, food availability, water composition, social

Fig. 1 Schematic view of the fish circadian system. In teleost fish the circadian system is made of more or less potent self-sustained units distributed in central and peripheral areas. The units are interconnected via nervous and/or hormonal pathways (arrows). They are directly and/or indirectly synchronized to the natural variations in photoperiod (yellow arrows) and temperature (thermometers) through photoreceptors and thermoreceptors located in the retina, pineal complex, deep diencephalon and skin. The pineal organ occupies a central position in the network through its rhythmic production of melatonin. Melatonin reaches multiple areas (red arrows), probably acting as a conductor/modulator of rhythms.

cues, rainfall, tides, and lunar cycles) may also provide input. Light is perceived through specific sensors, also located in different areas, including eyes, pineal gland, brain and skin (Baker *et al.*, 2015; Binder and McDonald, 2008; Chen *et al.*, 2014; Falcón *et al.*, 2010a,b).

How do all these different multi-oscillatory units get in tune? One hypothesis assumes the existence of one or several “master oscillators” that provide imprinting on “slave oscillators”. In this scheme, the pineal gland occupies a central position (Falcón *et al.*, 2010a,b). It is possible that this is by virtue of its rhythmic production of melatonin (Fig. 1).

The Pineal Gland and Melatonin

The pineal gland of fish contains functional photoreceptors, analogous to the retinal cones (Ekström and Meissl, 2010; Falcón *et al.*, 2010a,b). In most species, each pineal photoreceptor is a cellular circadian system by itself. At night, photoreceptors produce two kind of messages. One is an excitatory neurotransmitter, which stimulates the activity of second-order neurons (Ekström and Meissl, 2010). Light inhibits this release providing a highly sensitive indication on surrounding intensity. The neurons convey the nervous information to brain centers (Yáñez *et al.*, 2009) (Fig. 2). The other is melatonin produced from serotonin (Figs. 2 and 3) (Falcón *et al.*, 2010a,b). Light inhibits melatonin production, and the nocturnal rise is driven by intrinsic circadian clock machinery. Temperature controls the amplitude of the nocturnal surge in a species dependent manner (Figs. 2 and 3) (Falcón *et al.*, 2010a,b). It is worth mentioning that internal factors, including estradiol (E2), glucocorticoids, catecholamines, adenosine, GABA and melatonin itself, can also modulate this production (Falcón *et al.*, 2010a,b). Pineal melatonin is released into the blood and cerebrospinal fluid. The retina also produces melatonin however for autocrine/paracrine use only; it is catabolized *in situ*.

In some species, light perceived through the eyes contributes partially (seabass, cod) or totally (catfish, tilapia) to controlling pineal melatonin secretion (Bayarri *et al.*, 2003; Martínez-Chávez and Migaud, 2009), indicating a neural pathway connects the retina to the pineal. Finally, no circadian clock controls melatonin secretion in Salmonid fish, where melatonin production is just an on/off response to the LD information (Falcón *et al.*, 2010a,b).

In all cases, the pattern of the melatonin oscillations reflects the daily variations in light and temperature. Its secretion rhythm provides robust and reliable information on daily and calendar times. Melatonin is now recognized as the hormonal time-keeper of the organism (Falcón *et al.*, 2010a,b; Migaud *et al.*, 2010).

Melatonin Receptors

Melatonin acts through three subtypes of specific transmembrane receptors (MT1, MT2 and Mel1c), which may be duplicated, and displaying a wide distribution in nervous and peripheral organs (Falcón *et al.*, 2010a). Virtually all brain areas express one or another subtype (Herrera-Perez *et al.*, 2010; Mazurais *et al.*, 1999). The receptors are particularly abundant in the thalamus, optic tectum and cerebellum, in areas that generally integrate light signals from the retina and/or pineal neurons. It is interesting that the suprachiasmatic nuclei (SCN) and preoptic area (POA), two thalamic neuroendocrine centers, also receive pineal and retinal nerve endings (Yáñez *et al.*, 2009).

Fig. 2 Schematic view of the organization of the Brain/Pituitary/Gonads (BPG) axis in fish. The complex interactions at the different stages of the BPG axis are shown by the arrows (for details see text). Light and temperature inputs are shown by the yellow arrows and thermometers, respectively. Melatonin from the pineal gland (thick red arrows) acts at all levels of the axis. Neurons from the retina and pineal gland convey information to the hypothalamus (HPT) and preoptic area (POA). The sites of circadian clocks are shown by a clock. DA, dopamine; FSH, follicle-stimulating hormone; GnIH, gonadotropin inhibiting hormone; GnRH, gonadotropin releasing hormone; IgF, insulin like growth factor; Kiss, Kisspeptin; LH, luteinizing hormone; Vg, vitellogenin; NKb, NKf, neurokinins b and f.

The different melatonin receptor subtypes display daily variations (mRNA abundance, binding sites abundance or affinity for melatonin) (Bayarri *et al.*, 2010; Falcón *et al.*, 1996; Gaildrat *et al.*, 1998; Iigo *et al.*, 1994; Ikegami *et al.*, 2009) (Fig. 3). Binding sites abundance is generally higher during day than at night, but mRNA abundance may peak at different times of the LD cycle depending on the species and tissue investigated. These variations are maintained under constant, LL or DD, conditions in most but not all tissues, indicating a circadian clock control (Fig. 3) (Gaildrat *et al.*, 1998; Iigo *et al.*, 2003). Again, salmonid fish are an exception: no rhythm is detected under LL or DD (Amano *et al.*, 2006). Seasonal variations in abundance of melatonin mRNA or binding sites have also been described in the pituitary (Falcón *et al.*, unpublished), hypothalamus and optic tectum (Bayarri *et al.*, 2010) of seabass maintained under LD and LL, indicating control by a circannual clock. Finally, tropical species with lunar-cycles synchronized melatonin profiles, also display lunar-dependent expression of their melatonin receptors (Park *et al.*, 2014). In brief, studies on the effects of melatonin must consider the daily, lunar and/or seasonal variations of the hormone as well as of its receptors, which varies from a species to another and from an organ to another.

The Reproduction System

During the breeding season, levels of androgens rise in males, and those of estrogens and/or progestins rise in females, allowing gonad maturation and spawning behavior (Juntti and Fernald, 2016). This is under the control of the brain-pituitary-gonads (BPG) axis (Fig. 3). One main component of the BPG axis is the hypothalamic gonadotropin-releasing-hormone (GnRH), which

Fig. 3 Melatonin and its rhythmic biosynthesis from serotonin. Melatonin (*N*-acetyl-5-methoxytryptamine) is synthesized from serotonin in two steps: (1) The aralkylamine *N*-acetyltransferase (AANAT) catalyzes the conversion of serotonin into *N*-acetylserotonin (*N*-ac-serotonin); AANAT gene expression (*Aanat*) is controlled by intrinsic molecular clock machinery (clock); light inhibits AANAT protein abundance and activity while temperature controls amplitude of AANAT nocturnal activity (thermometers); (2) *N*-ac-serotonin is then methylated through the action of the acetylserotonin-*O*-methyltransferase (ASMT). The nocturnal surge in melatonin secretion results from the cyclic activity of AANAT. The duration of the nocturnal surge reflects the photoperiod, while its amplitude reflects the temperature. ASMT remains more or less constant throughout the light/dark cycle. The right panel shows the light/dark variations of each component during a 24 h cycle.

stimulates the synthesis and release of gonadotropins: follicle-stimulating hormone (FSH β) and luteinizing hormone (LH β), which in turn regulate steroidogenesis. Sex steroids are necessary for gametogenesis, and final gamete maturation (Zohar *et al.*, 2010). Sex steroids in turn exert diverse positive/negative feedback effects on tissues throughout the body (Fig. 3) with the cumulative effect of preparing multiple tissues for reproduction (Juntti and Fernald, 2016).

In distant teleost (perciforms), three isoforms of *Gnrh* exist: the hypophysiotropic *Gnrh1* in the pre-optic area/hypothalamus, *Gnrh2* in the midbrain tegmentum, and *Gnrh3* in the terminal nerve/ventral telencephalon (Powell *et al.*, 1994; Gothilf *et al.*, 1996). In early teleost (salmonids and cyprinids) only *Gnrh2* and *Gnrh3* isoforms have been identified; *Gnrh3* is believed to assume the non-redundant roles of *Gnrh1* (Zohar *et al.*, 2010). GnRH stimulation of gonadotropins secretion may be opposed by dopamine (DA) inhibition in some, but not all, teleost fish (Dufour *et al.*, 2010). Both the GnRH hypophysiotropic and DA inhibitory neurons are located in the preoptic area (POA) (Dufour *et al.*, 2010; Zohar *et al.*, 2010).

Other neuropeptides are involved in the control of reproduction acting upstream or downstream GnRH1/3 and DA; amongst the most significant are the gonadotropin inhibiting hormone (GnIH), Kisspeptins (Kiss1, Kiss2) and Neurokinins (NKb and NKf) (Paullada-Salmerón *et al.*, 2016; Zohar *et al.*, 2010) (Fig. 2).

1. GnIH, which belongs to the RFamide peptide family, has been reported to either inhibit (Paullada-Salmerón *et al.*, 2016; Spicer *et al.*, 2017) or stimulate (Biran *et al.*, 2014) gonadotropins. The time of year and experimental procedure used might explain these discrepancies. GnIH peptides interact functionally with GnRH neurons (Peng *et al.*, 2016; Spicer *et al.*, 2017), and reduce GnRH1 mRNA levels (Paullada-Salmerón *et al.*, 2016). An inverse relationship characterizes GnIH and GnRH mRNA abundance during the reproductive cycle of the carp (Peng *et al.*, 2016). In this species, three GnIH receptor subtypes are detected at all stages of the BPG axis, which also display seasonal variations in mRNA abundance. In the zebrafish, LPXRFamide antagonizes the Kiss2 activation of Kiss receptors (Spicer *et al.*, 2017).
2. Kiss1 and Kiss2 genes are expressed, respectively, in the *habenula*/medio-basal hypothalamus, and hypothalamus (Alvarado *et al.*, 2016). In the striped-bass and seabass, Kiss2 acts on the hypothalamus (targeting GnRH neurons) and the pituitary, in a stage- and sex-dependent manner (Alvarado *et al.*, 2016; Zmora *et al.*, 2014, 2015). This results in the upregulation of GnRH1, FSH β and LH β expressions and secretion for the latter two corresponding peptides. Kiss and Kiss receptors are also present in the gonads but their roles remain enigmatic.
3. NKb and NKf stimulate FSH β and LH β levels in the tilapia, zebrafish and goldfish pituitaries as well as *fsh* and *lh* mRNA and LH β release in the striped-bass (Zmora *et al.*, 2017). It also inhibits *kiss2* expression and stimulate *Gnrh* expression (Zmora *et al.*, 2017).

Melatonin and Reproduction: A Rhythmic Adventure

Virtually all components of the BPG axis display daily and annual variations (Cowan *et al.*, 2017). How these variations are linked to those of the environmental cues remains largely unknown (Juntti and Fernald, 2016). As a time-keeper of the organism, melatonin has drawn attention. Early studies have shown that photoperiod manipulation, together with pinealectomy or melatonin administration, could induce pro- or anti-gonadal effects or have no effect at all in fish (Falcón *et al.*, 2010a). A confusing picture thus arose, which most certainly results from the use of different species and sex, at different reproductive states and seasons, with different doses and ways of melatonin administration. Although the modalities of action are not always well understood, evidence points in favor of a role of melatonin in fish, provided by studies on the localization of melatonin receptors and the reported effects of the hormone at multiple levels of the BPG axis.

The Pituitary

The fish pituitary expresses melatonin binding-sites as well as MT1, MT2 and/or Mel1c mRNA receptors (Chai *et al.*, 2013; Gaildrat and Falcón, 2000; Ikegami *et al.*, 2009). And, cyclic-AMP from cultured pituitaries varies after melatonin challenge in pike and trout (Falcón *et al.*, 2010a). In the sea bass, MT2 mRNA abundance displays seasonal variations in an inverse relationship with the FSH β and LH β mRNA annual variations and reproductive status (Falcón *et al.*, unpublished). This agrees with the idea that melatonin inhibits gonadotropins as first demonstrated in the Atlantic croaker (Khan and Thomas, 1996). Other *in vivo* studies later confirmed an inhibitory impact of melatonin on GnRH, LH β or FSH β mRNA (pituitary), or protein abundance (pituitary or plasma) in the eel (Dufour *et al.*, 2010), Pacific salmon (Amano *et al.*, 2004) and Mediterranean seabass (Alvarado *et al.*, 2015). A clear-cut mechanism of action is however difficult to highlight because of differences in the experimental protocols and species studied. Thus, in masu salmon, melatonin administration inhibited permanently (FSH β), while inhibition of LH β and GnRH was transient (Amano *et al.*, 2004). In contrast, melatonin implants impacted neither the annual rhythm of pituitary gonadotropins mRNA abundance, nor plasma levels of FSH in the Mediterranean seabass, while the February peak of plasma LH β was slightly decreased (Alvarado *et al.*, 2015). This contrasts with *in vitro* studies showing inhibition of gonadotropins mRNA abundance by melatonin or melatonin analogs (Falcón *et al.*, unpublished). The differences might result from a combination of factors, including fish strains and experimental conditions (e.g., *in vitro* the possible interactions with other brain factors are disrupted). In euryhaline fish, water salinity might also be of importance. In the Mediterranean seabass, the annual variations in gonadotropins mRNA abundance (Alvarado *et al.*, 2015) was not affected by water salinity in marked contrast with all other pituitary hormones (Falcón *et al.*, unpublished). However, the *in vitro* response to melatonin was dramatically modified by previous adaptation to sea or fresh water. The time of the year at which the experiments are done is also of importance.

The Brain (POA/Hypothalamus)

Melatonin injected into the 3rd ventricle of the Atlantic croaker inhibited LH β release by the pituitary glands (Khan and Thomas, 1996). This, and the identification of melatonin receptors in various brain areas, including the POA and hypothalamus (Falcón *et al.*, 2010a; Migaud *et al.*, 2010), paved the way to studies dealing with the effects of melatonin on the different regulators of the pituitary function, including kisspeptins, GnRH, GnIH, and DA. In female zebrafish, *in vivo* melatonin treatment elevated *kiss1*, *kiss2* and *gnrh3* gene expression in the brain and LH β in the pituitary (Carnevali *et al.*, 2011). The effect on GnRH was probably indirect. Indeed (1) in the seabass, where GnRH1 and GnRH3 display LD variations and respond to melatonin, melatonin receptors co-localize with Kiss1/Kiss2, not GnRH (Alvarado *et al.*, 2015; Servili *et al.*, 2013); and (2) in the orange-spotted grouper, LD variations in the expression of MT1 melatonin receptors, *kiss2* and *gnrh1*, are consistent with the idea that melatonin regulates day/night variations of *gnrh1* expression through Kiss2; a decrease in MT1 receptors expression would increase the expression of *gnrh1* by upregulating *kiss2* expression (Chai *et al.*, 2013).

In the eel, melatonin implants did not affect *gnRH* mRNA abundance, while decreasing *fsh β* and *lh β* mRNA and steroids plasma levels (Dufour *et al.*, 2010). In this species, melatonin stimulates DA synthesis in brain areas known to innervate the pituitary. Such a mechanism might also operate in other species where melatonin/DA interactions have been detected. Melatonin administration lowers DA levels in the brain and/or pituitary of rainbow trout (Hernandez-Rauda *et al.*, 2000), three-spot wrasse (Takemura *et al.*, 2010) and carp during the spawning period (Popek *et al.*, 2010a), while it increases DA release from brain explants of sapphire devil (Badruzzaman *et al.*, 2013). In the latter two species, DA and melatonin rhythms appear inversely correlated (Badruzzaman *et al.*, 2013; Popek *et al.*, 2010b).

Interactions of melatonin with GnIH have been demonstrated in two fish species, the cinnamon clownfish (Nikaido *et al.*, 2010) and zebrafish (Yumnamcha *et al.*, 2017). In the former, GnIH and MT1 melatonin receptors co-localize in the hypothalamus. In the latter melatonin induces a dose-dependent decrease in *gnih* transcription *in vitro*.

The Gonads

Melatonin binding sites or receptors have been identified in the gonads of teleost fish (Chai *et al.*, 2013; Chatteraj *et al.*, 2009a,b; Ikegami *et al.*, 2009; Molina-Borja *et al.*, 1994). The receptors display daily and annual variations in an inverse relationship with serum

melatonin levels (Chattoraj *et al.*, 2009). Steroids and corresponding receptors also display daily and annual variations in association with the reproductive cycle. Photoperiod and temperature synchronize these variations (Zohar and Billard, 1984), which might involve a circannual clock because testosterone (T) and E2 rhythms are maintained under constant conditions in the killifish (Shimizu, 2003). The levels of T, 11-ketotestosterone, E2, and 17 α ,20 β -dihydroxy-4-pregnen-3-one (also known as maturation inducing steroid or MIS), rise during the breeding season (Juntti and Fernald, 2016). It is the increases in FSH β and LH β levels that promote steroidogenesis in the gonads. Sexual steroids contribute then to the process of gonadal maturation and spawning.

Melatonin mediates, at least in part, the effects of photoperiod on gonadal steroids. *In vivo* melatonin administration (1) mimics the effects of short days on GSI, gonadotropins and T, without affecting spermiation of masu salmon (Amano *et al.*, 2000); and (2) advanced testicular maturation during the preparatory phase, but was inhibitory during the pre-spawning and spawning phases, and ineffective during the post-spawning phase in the Indian carp (Bhattacharya *et al.*, 2007). *In vitro* studies support evidence of such complex and direct effects of melatonin on the gonads: (1) steroidogenesis in cultured trout ovarian follicles was stimulated by melatonin at early stages of development and became inhibitory at later stages, with a bimodal dose-dependent effect at maximum follicular growth (Leatherland and Lin, 2001); (2) in carps, pre-incubation of oocytes with melatonin prior to addition of MIS resulted in an accelerated rate of germinal vesical breakdown (Chattoraj *et al.*, 2008); (3) in the zebrafish melatonin increased the expression of two membrane progesterone receptor isoforms (*mpr α* and *mpr β*) (Carnevali *et al.*, 2011).

A permanent communication between the brain/pituitary complex and the gonads allows the activity of the different components of the BPG axis to be synchronized at all stages of the life cycle (Zohar *et al.*, 2010). Thus, steroids released by the gonads exert a feed-back control at different levels of the brain-pituitary axis. They also feed-back on the liver where they control VTG production (Specker and Sullivan, 1994). In the brain, the two major points of gonadal feedback regulation are the pituitary and the DA neurons of the POA. Steroids also modulate *gnRH* expression and content but the effects are mediated through Kiss neurons (Alvarado *et al.*, 2016; Zohar *et al.*, 2010). The pineal gland is also a target: *in vitro* (1) trout pineal cells express a E2 receptors, which mediate complex effects on melatonin secretion (Falcón *et al.*, 2010a,b); and (2) in the catfish E2 and T inhibit one enzyme of the melatonin pathway and hence melatonin synthesis (Yanthan and Gupta, 2007).

Thyroid Hormones and the *Saccus Vasculosus*

Thyroid hormones, triiodothyronine (T3) and thyroxine (T4), control energy metabolism and growth, and regulate development and differentiation of tissues. The hypothalamic thyrotropin-releasing hormone (TRH) produced by cells in the POA stimulates the production of pituitary thyroid-stimulating-hormone (TSH β). In turn TSH stimulates the production of T4 and T3 by the thyroid follicles, but most of the T3 present in the circulation is obtained *via* the conversion of T4 to T3 by deiodinases (DIO) (Swapna and Senthilkumaran, 2007). Evidence linking thyroid hormones and reproduction is extensively documented elsewhere (Duarte-Guterman *et al.*, 2014; Flood *et al.*, 2013; Swapna and Senthilkumaran, 2007) and annual variations in T3/T4 production have been correlated with seasonal reproduction in several fish species (Cowan *et al.*, 2017). TSH and DIO have also been identified in the coronet cells of the SV of masu salmon where abundance of *tsh β* mRNA, *dio2* mRNA and/or the corresponding proteins display light dependent changes *in vivo* and *in vitro* (Nakane and Yoshimura, 2014). Coronet cells also express photopigment genes. Finally, removal of the SV abolished the short-photoperiod induced testicular growth in the fish. In the SV of the Atlantic salmon, both Kiss receptors and GnRH3 transcripts were detected in another cell type than the coronet cells, perhaps the cerebrospinal fluid contacting cells, albeit at lower levels than in the brain (Chi *et al.*, 2017). In addition, transcripts variations mirrored those in the brain in fish maintained under different photoperiodic conditions. Together, these data suggest that the SV contributes to regulating photoperiodic fish reproduction.

Photoperiodism in Fish Farming

The photoperiod control of gametogenesis, reproductive seasonality, and the subsequent interactions between reproduction and growth, have been implemented in broodstock management and performance optimization in commercial fish farming (Migaud *et al.*, 2010). Manipulated photoperiod and temperature regimes are routinely used in commercial broodstock operations to phase-shift the spawning season and obtain eggs all year round (Migaud *et al.*, 2010; Zohar *et al.*, 1995). Additionally, when fish in production systems enter gametogenesis and reproductive development, growth rate is significantly diminished due to a shift in utilization of energy sources toward gonadal growth instead of somatic growth (Good and Davidson, 2016; Taranger *et al.*, 2010). This represents a major obstacle in commercial aquaculture, as many species start gametogenesis before reaching market size. Long photoperiods have been implemented to prevent precocious sexual maturation in large-scale commercial systems, such as floating netpens or land-based tanks, in which submerged or overhead lights are used to extend the duration of the daylight hours (Porter *et al.*, 1999).

Conclusions

The control of reproduction involves a complex network of actors as summarized in Fig. 3. Most of the network components display daily and annual variations so that reproduction events occur at the right time of the day and year. Photoperiod and

temperature are the two main external synchronizers of the system that act through sensors located in different organs and tissues. The pineal gland is one of them. Evidence accumulates indicating that melatonin, its hormonal output, plays a major role in transducing photoperiodism to reproduction, acting at different levels of the network (Fig. 3). Melatonin might be considered a harmonizer or conductor of a concert of rhythms. No generalized model on the effects and roles of melatonin can be drawn; perhaps “several models” exist among the ~30,000 fish species listed. Differences between species have been highlighted and too few have been thoroughly investigated. Also, studies need to be exhaustive, considering sex and age of the fish investigated, time of day and year, water salinity and composition, etc. Indeed, melatonin appears to have multiple and sometimes complex effects on the reproductive system as well as on other neuroendocrine regulations more or less related to reproduction. To date such studies are lacking and attempts targeted mainly aquaculture fish, which do not necessarily behave and function like the wild counterparts. The necessary comparative studies will not only contribute to our understanding of fish biology and evolution, they should also help implementing conservation policies. This is indispensable in light of the ever-increasing anthropogenic pressures that fish are facing. The negative effects of intensive fisheries, physical and chemical pollution, reduction of wild natural spaces and global climate change (ocean acidification, temperature rise) are more than additive and put survival of species into challenge. A better knowledge of fish physiology and behavior will also allow a better management of fisheries policies and benefit the aquaculture industries. The large variability in regulatory systems, sensitivities and responses observed mean that species-specific regimes should be implemented in commercial settings to improve and standardize husbandry practices (e.g., use of light quality and intensity, temperature, etc.) in fish indoors and outdoors aquaculture.

Seasonal Reproduction: Photoperiodism, Birds

Photoperiodism and Seasonal Reproduction in Birds

In mid to high latitude regions, climatic conditions such as temperature, humidity, rainfall, and day-length, fluctuate dramatically throughout the year. Of these conditions, changes in day-length are precise and predictable. Therefore, animals inhabiting these regions exhibit sophisticated physiological and behavioral responses (molting, migration, etc.) to changing day-length (photoperiod), using it as a calendar, so to speak. This phenomenon is called "photoperiodism". In early spring, songbirds sing to attract females and declare territorial demarcations. In alpine regions, rock ptarmigans completely change the color of their feathers throughout the year. Several types of birds (e.g., the Arctic tern) are migratory and generally follow the same annual migratory routes. In addition, offspring of birds and other animals hatch or are born in spring through summer because of the abundance of food and mild climates. The time at which mating occurs in animals is dependent on their inherent period of egg incubation or gestation, where the precise timing of mating events accounts for the length of the incubation/gestational period (i.e., the longer the incubation/gestational period, the earlier the mating event). This reproductive strategy is known as "seasonal reproduction." Hamsters, medaka fish, etc. mate in the spring/summer and are called long-day seasonal breeders; while sheep, emu, masu salmon, etc. mate in fall/winter and are called short-day seasonal breeders. Generally, most non-tropical birds are long-day seasonal breeders owing to the length of the egg incubation period.

A Model Animal for Avian Photoperiodism

As previously described, most avian species are long-day seasonal breeders, and begin their reproductive activity when the photoperiod elongates. It is known that the photoperiodic responses of avian gonads are very robust and rapid. Avian species exhibit seasonal changes in their gonads, where the weight of the testes can increase or decrease more than one hundred-fold within a few weeks.

The first study on photoperiodism in vertebrates was reported in avian species by Rowan in 1925. Rowan demonstrated that gonadal development in the dark-eyed junco, a non-tropical bird, occurred in response to changes in photoperiod (Rowan, 1925). Japanese quails are ideal subjects for studying the mechanisms of seasonal reproduction because of their availability, ease of care, and drastic photoperiodic response. They rapidly increase plasma levels of hormones that stimulate the activity of the gonads (i.e., gonadotropins), such as luteinizing hormone (LH) and follicle-stimulating hormone (FSH), in response to the changing length of the photoperiod. For instance, plasma LH concentration increases on the first day that there is a shift from short-day conditions to long-day conditions (Nakao *et al.*, 2008). Remarkably, after only two weeks of photoperiod elongation, the weight of their testes had reached full size.

It is thought that photoperiodism consists essentially of three systems, (1) photoreceptors which detect the light information of photoperiod, (2) circadian clocks which measure the length of photoperiod, and (3) endocrine system which transmit the light information to internal endocrine information (e.g., hormones). Japanese quails have been used in studies about these all systems owing to their most appropriate natures.

Relationship Between Mediobasal Hypothalamus and Photoperiodism

Series of studies using Japanese quails have revealed that the mediobasal hypothalamus (MBH) is the key region in the brain in the control of photoperiodic responses (Fig. 1). Lesions in the MBH have been shown to block the photoperiodic response under long-day conditions (Sharp and Follett, 1969). On the other hand, electric stimuli to the MBH enhanced plasma LH concentrations. The protein Fos, which is encoded by an immediate early gene *c-fos* and is often used as a marker for neuronal activity following stimulation, was reported to be induced in the MBH in response to a single long-day stimulus (Meddle and Follett, 1995). Therefore, the MBH has been considered to be the key region for photoperiodism in avian brain.

Local Activation of Thyroid Hormones in the Mediobasal Hypothalamus

Thyroid hormones are thought to regulate the plasticity and development of the central nervous system. The involvement of thyroid hormones in seasonal reproduction has been a focus of scientists for a long time, and it has been suggested that the responses of birds to prolonged photoperiod are related to changes in thyroid hormones. It has been reported that removing the thyroid gland prevented a seasonal reproductive response, while injecting thyroid hormones enhanced LH secretion and gonadal development in several species of vertebrates. Thyroxine (T₄), a prohormone of thyroid hormones, is catalyzed to the bioactive form, 3,5,3'-triiodothyronine (T₃) by type 2 deiodinase (DIO2), whereas T₃ is catalyzed to inactive diiodothyronine (T₂) by type 3 deiodinase

Fig. 1 In avian species, the mediobasal hypothalamus (MBH) is thought to be a key brain region in photoperiodism. Birds detect light information for photoperiod via deep brain photoreceptors where the photosensitive proteins, called opsins (rhodopsin, melanopsin, VA-opsin, and Opsin 5) are expressed. Light information is delivered to the pars tuberalis of the pituitary gland (PT) and induces the secretion of thyroid-stimulating hormone (TSH) to the MBH. TSH triggers an increase in DIO2 expression in the ependymal cells (ECs) and the local activation of thyroid hormones (T4 to T3 conversion). Activated thyroid hormone T3 alters a morphological change in GnRH-nerve terminals and glial cells, and photoperiodically control GnRH secretion to gonadotrophs in the pars distalis of the pituitary gland (PD). (Modified from Nakane, Y., Yoshimura, T., 2014. Universality and diversity in the signal transduction pathway that regulates seasonal reproduction in vertebrates. *Front Neurosci.* 21(8), 115. doi: 10.3389/fnins.2014.00115. eCollection 2014.)

(DIO3). Interestingly, it has been found that *DIO2* mRNA increases in ependymal cells (ECs)-which form the epithelial lining of the ventricles in the brain and the central canal of the spinal cord-in the third ventricle of MBH, showing that T3 levels are light-induced within the MBH in quails under long-day conditions. In addition, thyroid hormone receptors, such as TR α and TR β are expressed in the MBH in quails (Yoshimura *et al.*, 2003).

In the median eminence (ME), (the part of the hypothalamus that is responsible for the release of regulatory gonadotropin-releasing hormone (GnRH)), within the MBH, there are abundant quantities of GnRH-nerve terminals projecting to the basal lamina (basement membrane) adjacent to the pituitary gland. It is thought that GnRH secretion is under the control of GnRH-nerve terminals rather than the somata of GnRH neurons. In quails, it has been observed that most GnRH-nerve terminals are encased in glial cells and do not approach the basal lamina under short-day conditions, while the nerve terminals directly contact the basal lamina under long-day conditions. It is also worth noting that the concentration of GnRH-nerve terminals does not appear to change between short-day conditions and long-day conditions. Interestingly, T3 implantation into the MBH of the quail under short-day conditions mimics the aforementioned morphological changes in GnRH-nerve terminals and glial cells (Yamamura *et al.*, 2006). It is thought that the local activation of thyroid hormone within the MBH causes GnRH-nerve terminals to approach to the pituitary gland, resulting in the photoperiod-dependent acceleration of GnRH secretion. The morphological plasticity observed in the GnRH-nerve terminals and glial cells of quails has also been observed during the reproductive cycle in rats and sheep. It is possible that the local elevation of active thyroid hormone in the MBH is a key event in seasonal reproduction in vertebrates (Fig. 1).

Thyroid-Stimulating Hormone Triggers Local Thyroid Hormone Activation

The analysis of wide range of genes expressed in the MBH have revealed that mRNA coding the beta subunit of thyroid-stimulating hormone (*TSHB*) is induced in the pars tuberalis (tuberal part) of the pituitary gland (PT) approximately 16 h after dawn in quails that have shifted from short-day to long-day conditions. After the temporal increase of *TSHB* mRNA, the expression of *DIO2* mRNA is also photoinduced in the ECs expressing the TSH receptor (TSHR). The intraventricular injection of TSH into quails under short-day conditions resulted in the induction of *DIO2* mRNA in the ECs (Nakao *et al.*, 2008). Thyrotrophs are cells that are responsible for the production, secretion of TSH, and they are distributed in the pars distalis (distal part) of the pituitary gland (PD), as well as in the PT. Thyrotrophs are thought to essentially be under the control of thyrotropin-releasing hormone (TRH), which is derived from part of the hypothalamus. Interestingly, the application of TRH or T4 can alter the expression of *TSHB* mRNA in the PD, but not in the PT, suggesting that TSH in the PT is under the control of changing the length of photoperiod, not of TRH. Therefore, at dusk of the first day of transfer to long-day conditions, TSH derived from the PT triggers the local activation of thyroid hormone through *DIO2* expression in the MBH in avian species. However, the transport system of PT- derived TSH to the ECs remains unclear (Fig. 1).

Detection Light Information Via Deep Brain Photoreceptors

In mammals, it is believed that the eye is the only photoreceptive organ, whereas non-mammalian vertebrates have extraretinal photoreceptors located in pineal organs and deep brain regions. It is thought that avian species detect light via deep brain photoreceptors. Historically, the existence of deep brain photoreceptors has been first indicated in the European minnow. The first study reporting deep brain photoreceptors in birds was performed by Benoit (1935), where ducks with black caps covering their heads did not exhibit photoperiodic responses in their gonads (Benoit, 1935). In addition, house sparrows that had black ink injected under their head skins also failed to exhibit any photoperiodic response in their gonads. Gonadal development takes place even in blinded and pinealectomized quails, and local illumination to several deep brain regions using light fibers and light-emitting beads elicited testicular development in sparrows and Japanese quails. It is worth noting that a broad range of wavelengths of light can penetrate the skin, and it has been suggested that light can also penetrate the skull and into the brains of various vertebrates including birds (Hartwig and van Veen, 1979). In fact, it has reported that various photosensitive proteins, called opsins, are expressed in deep brain regions of various avian species. The expression of rhodopsin, which is responsible for visual system in the retina, has been found in the area of forebrain, called lateral septum organ (LSO), in pigeons (Fig. 2(A)). In addition, the expression of rhodopsin in the brain has been reported in other avian species such as ring doves, ducks, and quails. Melanopsin, which is expressed in the intrinsically photosensitive retinal ganglion cells (ipRGCs) of the retina, is localized in the forebrain and the hypothalamus of chicken and turkey. Vertebrate ancient (VA)-opsin is also known to be expressed in the hypothalamus of chicken. Opsin 5 was reported to be localized in the cerebrospinal fluid (CSF)-contacting neurons of the paraventricular organ (PVO) in Japanese quails and chicken (Nakane *et al.*, 2010). The PVO is located within the MBH, where lesions around the PVO attenuate photoperiodic testicular development in Japanese quails (Sharp and Follett, 1969). CSF-contacting neurons, which are also present in the LSO, have been considered to be candidate deep brain photoreceptors

Fig. 2 (A) It has been reported that avian species have photoreceptors in several brain regions (red ellipses). Cerebrospinal fluid (CSF)-contacting neurons are distributed in the lateral septum organ (LSO) and paraventricular organ (PVO). (B) Representative image for Opn5-expressing CSF-contacting neurons and schematic image for CSF-contacting neurons in the paraventricular organ (PVO). A picture of cells stained brown shows where the Opn5 protein is expressed. They possess 9×2+0 cilium. Rod cells, cone cells, and photoreceptive cells in the pineal organ have the same cilium. Scale bars indicate 20 μm . (Modified from Nakane, Y., Yoshimura, T., 2014. Universality and diversity in the signal transduction pathway that regulates seasonal reproduction in vertebrates. *Front Neurosci.* 21(8), 115. doi: 10.3389/fnins.2014.00115. eCollection 2014.

because of their unique morphological nature. CSF-contacting neurons have knob-like terminals, and are thought to morphologically resemble photoreceptive cells in developing retina (Vigh-Teichmann *et al.*, 1980; Fig. 2(B)). In fact, it has been reported that Opn5-expressing CSF-contacting neurons have intrinsic electrophysiological photosensitivity (Nakane *et al.*, 2014).

Circadian Clocks and Photoperiodism

In Japanese quails, when the light period exceeds 12 h, gonads begin to develop. This threshold photoperiod is called the “critical photoperiod.” The critical photoperiod has also been observed in starlings. On the other hand, consecutive and long photoperiods are not necessarily required for gonadal development. Photostimuli in the afternoon are still able to promote gonadal development in finches under short-day conditions (Fig. 3; Hamner, 1963). This photosensitive time zone is called the “photoinducible phase”. White-crowned sparrows under constant darkness are still able to develop their gonads when exposed to a photostimulus early in the evening, where photoinducible phase still occurs in a 24-h cycle. This means that the emergence of the photoinducible phase is under the control of an endogenous circadian clock (also known as circadian rhythm). It is well known that the circadian clock occurs via negative autoregulatory feedback loops owing to the transcription/translation of clock genes (e.g., *CLOCK*, *BMAL1*, *PER*, *CRY*, etc.). Clock genes in vertebrates were first reported in mammalian species. In mammals, the suprachiasmatic nucleus (SCN), which located in the dorsal region of the optic chiasma, and is known to be the only master clock of circadian rhythm. In contrast, in avian species, it is thought the pineal organ and retina are the master clocks of circadian rhythm along with the SCN. These master clocks have been reported not to affect photoperiodism, which indicates the possibility that alternative clocks define the photoinducible phase. Although changing the length of photoperiod does not affect the expression of clock genes in the MBH, the expression of the clock gene *CRY1* in the PT is induced when photostimulus is exposed to photoinducible phase (Yasuo *et al.*, 2004). It is possible that clock genes expressed in this region trigger the emergence of photoinducible phase. Despite all we know, the mechanisms by which avian species, as well as the other vertebrates, measure the length of photoperiod still remain a huge mystery.

Fig. 3 Schematic drawing for photoinducible phase. A single white-colored box indicates 6-h light period, whereas black-colored box or bar means dark period. The effect of 6-h photostimulus exposed to house finch at various intervals after entry to darkness on testicular size (Hamner, 1963). Photoinducible phase where testes develop in response to the photostimulus emerges in approximately a 24-h cycle. Photoinducible phase is thought to be governed by an endogenous circadian clock. However, the detailed mechanism is yet unclear in any vertebrate species.

Seasonal Gonadal Regression

“Photorefractoriness” is the eventual regression of gonads as a result of a prolonged long-day conditions. At higher latitudes, where the breeding season is shorter, non-tropical species show remarkable photorefractoriness. In addition, a recent study indicated that short days and low temperature affect seasonal testicular regression in quails, where short-day stimuli lead to a reduction in testicular weight and low-temperature accelerates this regression. The more testicular growth decreased, the more plasma T3 concentration increased. Likewise, the daily peripheral administration of T3 to quails also caused testicular mass to decrease. These findings indicate that low temperature induces the increase in the plasma T3, as well as subsequent seasonal gonadal regression (Ikegami *et al.*, 2015).

Conclusion

In avian photoperiodism, long-day information detected via deep brain photoreceptors, (not eyes and pineal organs) stimulate the expression of TSH in the PT. Photoinduced TSH secreted from the PT has a role as a master regulator for local activation of thyroid hormone within the MBH. Activated thyroid hormone is thought to trigger the morphological change of GnRH-nerve terminals and control the seasonal change of GnRH secretion. However, mechanism involved in measuring the length of photoperiod remains a huge enigma not only in avian species but also in other vertebrates. Although seasonal reproduction is essentially under the control of photoperiod, seasonal regression in gonads seems to be involved in both photoperiod and temperature.

Glossary

Arginine vasopressin (AVP) A form of a peptide, vasopressin, in which the eighth amino acid residue of the total nine amino acid residues is an arginine residue.

Arylalkylamine N-acetyltransferase (AANAT) An enzyme that is involved in the production of melatonin from serotonin.

Clock genes Circadian clock genes, including Period (Per) 1, 2, 3, Cryptochrome (Cry), Brain and muscle ARNT-like 1 (Bmal1), and Circadian locomotor output cycle kaput (Clock).

Cyclic adenosine monophosphate (cAMP) An intracellular signaling molecule important in many biological processes. cAMP is a derivative of adenosine triphosphate (ATP).

Dopamine A catecholamine that plays important roles in the brain such as reward and motor control.

Estradiol A steroid hormone that regulates estrous and menstrual cycles. Estradiol is produced in ovaries, but testosterone can be aromatized into estradiol.

Gonadotropin Glycoprotein polypeptide hormones, including follicle-stimulating hormone (FSH) and luteinizing hormone (LH), secreted by gonadotrope cells of the anterior pituitary gland.

Gonadotropin-inhibitory hormone (GnIH) A hypothalamic neuropeptide that suppresses gonadotropin synthesis and release from the anterior pituitary gland.

Gonadotropin-releasing hormone (GnRH) A hypothalamic neuropeptide that stimulates gonadotropin synthesis and release from the anterior pituitary gland.

Hypophyseal portal system Blood vessels that connects the median eminence in the hypothalamus with the anterior pituitary gland. Neuropeptides released in the median eminence are transported to the anterior pituitary gland through this system.

Hypothalamic-pituitary-gonadal (HPG) axis Hypothalamic neuropeptides, GnRH, GnIH and kisspeptin, control gonadotropin secretion from the anterior pituitary gland, and gonadotropin regulates estradiol and testosterone secretion as well as oogenesis and spermatogenesis in the ovary and testis, respectively.

Kisspeptin A hypothalamic neuropeptide that is involved in the stimulatory regulation of GnRH neurons.

Melanopsin A photopigment in retinal ganglion cells that communicate directly to the suprachiasmatic nucleus (SCN) in the brain.

Melatonin A hormone produced in the pineal gland and involved in the regulation of circadian rhythms, including sleep-wakefulness and seasonal reproduction.

Noradrenaline A catecholamine that plays important roles in the brain such as arousal and fight-or-flight response.

Pars tuberalis A part of the anterior pituitary covering the pituitary stalk.

Pineal gland An endocrine gland located in the epithalamus and produces melatonin.

Suprachiasmatic nuclei (SCN) A region in the hypothalamus above the optic chiasm. SCN generates circadian rhythms by circadian transcription of clock genes.

Testosterone A steroid hormone responsible for development of male reproductive organs and behavior.

Thyroid hormones Hormones produced by the thyroid gland, including triiodothyronine (T_3) and its prohormone thyroxine (T_4), responsible for regulation of metabolism.

Thyroid-stimulating hormone (TSH) An anterior pituitary hormone that stimulates the thyroid gland to produce T_4 and T_3 .

Type 2 deiodinase (Dio2) An enzyme that converts T_4 to T_3 .

Type 3 deiodinase (Dio3) An enzyme that inactivates T_4 and T_3 .

Vasoactive intestinal polypeptide (VIP) A vasoactive peptide hormone produced in many tissues including the gut, pancreas, and SCN of the hypothalamus.

Introduction

Photoperiodism is an organisms' ability to adjust their physiology and behavior to seasonal changes in the environment according to the length of day (photoperiod), because photoperiod is the most reliable information to detect the time of year. Many mammals that live in high latitude use photoperiod to time breeding so that mothers can raise their offspring when foods are available and the climate is favorable, which can maximize the survival and growth of the offspring. Long day (LD) breeders include relatively large animals such as horse and bear that have gestation period of about a year and relatively small animals such as hamsters that have

short gestation period of few weeks so that they can deliver their baby in spring or summer. On the other hand, short day (SD) breeders include medium size animals such as sheep and goats that have gestation periods of about half a year so that they can deliver their baby in spring.

Sunlight is detected in eyes and photic information is transmitted to the suprachiasmatic nuclei (SCN) in the brain through the retinohypothalamic tract (Fig. 1). The SCN contain the master biological clock and adjust the master clock according to photic information received. The SCN regulate the pineal gland through several synaptic pathways and enable nocturnal secretion of melatonin from the pineal gland. Reproductive activities are regulated by the hypothalamic-pituitary-gonadal (HPG) axis (Fig. 1). In the hypothalamus, neuropeptides such as gonadotropin-releasing hormone (GnRH), gonadotropin-inhibitory hormone (GnIH) and kisspeptin play their roles to regulate gonadotropin secretion from the anterior pituitary, which regulate gonadal development and maintenance (Fig. 1). Photoperiodic reproductive activities depend on the ability of the HPG axis to read melatonin concentration that is a reliable endogenous indicator of day length. Here, we describe how model animals of photoperiodism, sheep (SD breeder) and hamsters (LD breeder), employ common and distinctive mechanisms to regulate reproduction according to season.

Retinohypothalamic Tract

The retinohypothalamic tract originates in retinal ganglion cells that contain melanopsin as the photopigment. The photic information sensed in the retinal ganglionic cells are monosynaptically transmitted to the SCN through the optic nerve (Fig. 1).

SCN

SCN neurons maintain their circadian rhythmicity by transcriptional auto-regulatory loop between the clock genes and their translated proteins. Per (Period 1, 2, 3), Cry (Cryptochrome), Bmal1 (Brain and muscle ARNT-like 1), and Clock (Circadian locomotor output cycle kaput) are the major clock genes that generate circadian rhythmicity in the SCN. Transcription of Per1 and Per2 is activated by photic signals and regulates the expression of Bmal1, which dimerizes with Clock to enhance circadian

Fig. 1 Mechanism of how light-dark information is sensed in the eye and conveyed and translated in the retinohypothalamic tract, brain, thoracic spinal cord, superior cervical ganglion, pineal gland and pituitary to regulate gonadal activity according to season in photoperiodic mammals. Arc, arcuate nucleus; DA, dopamine; Dio2, type 2 deiodinase; E2, estradiol; FSH, follicle-stimulating hormone; GnIH, gonadotropin-inhibitory hormone; GnRH, gonadotropin-releasing hormone; Kiss, kisspeptin; LH, luteinizing hormone; ME, median eminence; PT, pars tuberalis; PVN, paraventricular nucleus; SCN, suprachiasmatic nuclei; T, testosterone; TSH, thyroid-stimulating hormone. Solid lines indicate direct regulation, whereas dotted lines indicate indirect regulation.

transcriptional activity of Per and Cry. Additionally, Per and Cry dimerize and repress Clock/Bmal1-induced transcriptional activity (Panda *et al.*, 2002).

The SCN can be divided into two major subdivisions ventrolateral (vl) SCN, the core, and the dorsomedial (dm) SCN, the shell. The vlSCN is the conductor of rhythmicity and transmits synchronizing cues to the dmSCN. vlSCN contains cell bodies producing a neuropeptide, vasoactive intestinal polypeptide (VIP), and dmSCN contains cell bodies producing another neuropeptide, arginine vasopressin (AVP). VIP neurons project to GnRH neurons in the preoptic area (POA), whereas AVP neurons project to kisspeptin neurons in the anteroventral periventricular nucleus (AVPV). Although direct innervation of hypothalamic neurons by SCN neurons are studied in terms of the regulation of female estrous or menstrual cycle, their role in photoperiodism is not understood.

Photoperiodic information processed in the SCN is transmitted to the pineal gland through a polysynaptic pathway, first to the paraventricular nucleus (PVN) then to the intermediolateral cell column of the thoracic spinal cord, the superior cervical ganglion and through the postganglionic noradrenergic fibers to the pineal gland (Fig. 1; Coomans *et al.*, 2015).

Pineal Gland and Melatonin

Noradrenaline is released from the fiber endings of the superior cervical ganglionic neurons during night to the pinealocytes in the pineal gland (Coomans *et al.*, 2015). Cyclic adenosine monophosphate (cAMP) level increases in the pinealocytes when $\beta 1$ and $\alpha 1$ adrenergic receptors are activated by noradrenalin. This elevated cAMP activates a key enzyme in melatonin synthetic pathway, arylalkylamine N-acetyltransferase (AANAT), resulting in rhythmic synthesis and secretion of melatonin during night (Klein *et al.*, 1970; Klein and Weller, 1970). Melatonin level is high during night in both diurnal and nocturnal animals. This melatonin rhythm conveys photoperiodic information to the hypothalamus and pituitary. Long duration of melatonin decodes short day length in fall and winter, whereas short duration of melatonin decodes long day length in spring and summer.

HPG Axis

Reproductive activities of mammals are ultimately regulated by the HPG axis. GnRH stimulates synthesis and release of gonadotropins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH), from the anterior pituitary gland. Gonadotropins act on the testis and ovary to stimulate steroidogenesis such as testosterone synthesis in male and estradiol (E2) synthesis in female and gametogenesis such as spermatogenesis and oogenesis. Testosterone or E2 not only feeds back to the hypothalamus and pituitary to adjust gonadotropin secretion but also facilitate reproductive behaviors by acting on the brain. GnIH and kisspeptin are relatively newly discovered hypothalamic neuropeptides that regulate the HPG axis (Fig. 1; Kriegsfeld *et al.*, 2015; Clarke and Arbabi, 2016; Ubuka *et al.*, 2016).

GnRH

Schally's and Guillemin's groups independently isolated and identified mammalian GnRH peptide from pig and sheep brains, respectively, in the early 1970s. Neuronal cell bodies producing GnRH exist in the preoptic area (POA) and send their axons to the median eminence (ME) (Fig. 1). GnRH is released at the ME into the hypophyseal portal system in a pulsatile manner and carried to the anterior pituitary gland. Gonadotropes that produce gonadotropins in the anterior pituitary gland express GnRH receptor and LH is released in a pulsatile manner following GnRH pulses (Levine *et al.*, 1982). GnRH pulse frequency is low in the non-breeding season and increases in the breeding season (Barrell *et al.*, 1992). GnRH pulse frequency in breeding season fluctuates according to estrous (menstrual) cycle in females but GnRH pulse amplitude in breeding season always exceeds that of non-breeding season (Barrell *et al.*, 1992).

GnIH

GnIH was discovered in Japanese quail as the first inhibitory hypothalamic neuropeptide of gonadotropin release (Tsutsui *et al.*, 2000). GnIH peptide was isolated and identified in various mammalian species including hamsters, monkeys and humans (Ubuka *et al.*, 2016). GnIH is also named RFamide-related peptide in mammals, because GnIH peptides have LPXRFamide (X = L or Q) amino acid sequence at their C-termini. GnIH neuronal cell bodies exist in the dorsomedial hypothalamic area (DMH) in mammals and terminate on GnRH and kisspeptin neurons that express GnIH receptors (Fig. 1). Expression of GnIH peptide and GnIH neuronal activities are regulated by natural and social environmental cues and stress. Therefore, one of the important roles of GnIH is to convey favorable and unfavorable environmental and social information to the HPG axis (Ubuka *et al.*, 2016).

Kisspeptin

Kisspeptin is also a relatively newly identified neuropeptide that is involved in the stimulatory regulation of GnRH neurons (Clarke and Arbabi, 2016). Two clusters of neuronal cell bodies that synthesize kisspeptin exist in the hypothalamus. In rodents, kisspeptin synthesizing neuronal cell bodies in the AVPV are involved in the regulation of GnRH/LH surge by positive feedback of E2 in cycling female. On the other hand, kisspeptin synthesizing neurons in the arcuate nucleus (ARC) are involved in the negative regulation of GnRH/LH pulse by testosterone or E2. Thus, kisspeptin plays an important role in the positive and negative regulation of GnRH/LH release by sex steroids. Kisspeptin neurons in the Arc play significant roles in seasonal regulation of the HPG axis (Fig. 1).

Photoperiodic Regulation of the HPG Axis in Sheep and Hamsters

Sheep: SD Breeders

Photoperiodism has been extensively studied in female sheep. Reproductive activity of adult female sheep is comprised of breeding season consisting of ovarian activity and ovulation in SD (fall and winter), and non-breeding anestrus season a period of ovarian quiescence and anovulation in LD (spring and summer) (Table 1; Weems *et al.*, 2015). This seasonal variation of ovarian activity is the result of changes in responsiveness of GnRH neurons to negative feedback actions of E2 and steroid-independent inhibition of GnRH neurons (Weems *et al.*, 2015). Sheep can become photorefractory if LD or SD was artificially prolonged and they show circannual changes in reproductive activity due to endogenous interaction of the HPG axis.

E2 gains the ability to suppress the frequency of GnRH/LH pulses during anestrus season even if E2 concentration is low in LD (Table 1). It is thought that E2 acts on estrogen receptor α expressing glutamate neurons in the ventromedial POA and retrochiasmatic area, and these neurons stimulate A15 dopamine neurons that directly act on GnRH neuronal terminals or indirectly on kisspeptin neurons in the Arc to inhibit GnRH pulse frequency. As the number of kisspeptin neurons in the Arc decreases due to stronger inhibition by E2 in anestrus season GnRH/LH pulse frequency decreases (Table 1; Weems *et al.*, 2015).

Pinealectomy of female sheep causes free running circannual rhythm of reproductive activity and inactivity and melatonin infusion for 3 months can synchronize reproductive rhythms suggesting that melatonin adjusts endogenous circannual rhythm of female sheep. Dardente *et al.* (2008) examined the expression pattern of GnIH in Soay sheep acclimated to LD or SD. GnIH was expressed widely in the hypothalamus and showed a generally moderate increase in LD. On the other hand, GnIH expression in the ependymal cells surrounding the base of the third ventricle was highly photoperiodic, which was undetectable in SD but consistently high under LD (Dardente *et al.*, 2008). These results suggest that long duration of melatonin secretion inhibits GnIH expression that allows higher GnRH neuronal activity in SD (Fig. 1; Table 1).

Melatonin receptor is most highly expressed in the pars tuberalis (PT) which is part of the anterior pituitary covering the pituitary stalk (Fig. 1; Klosen *et al.*, 2002). Thyroid hormones (T_3 and T_4) are thought to be critical for the transition from breeding to anestrus because thyroidectomy makes the sheep keep the breeding state but T_4 replacement can restore reproductive transition to anestrus. On the other hand, thyroid hormones are not required for the transition from anestrus to breeding state in sheep. Recent studies suggest that LD melatonin pattern increases the expression of a transcription factor, *eyes absent 3*, which stimulates thyroid stimulating hormone (TSH) synthesis in the PT. TSH diffuses in the nearby tissue and stimulates the expression of type 2 deiodinase (Dio2), an enzyme that converts T_4 to T_3 , and T_3 induces GnRH secretion. LD has an opposite effect on type 3 deiodinase (Dio3), an enzyme that inactivates T_4 and T_3 in sheep (Fig. 1; Table 1; Weems *et al.*, 2015).

Hamsters: LD Breeders

Hamsters are LD breeders that breed in spring and summer in the wild. However, if hamsters are artificially kept in constant SD and they will become photorefractory and they grow and maintain their high gonadal activity. Hamsters do not become photorefractory to artificial constant LD and they maintain their high gonadal activity.

The duration of melatonin secretion is the key signal that regulates the HPG axis in hamsters (Kriegsfeld *et al.*, 2015). DMH is the potential target to read melatonin signal for photoperiodic regulation of the HPG axis because it expresses both sex steroid and melatonin receptors and is essential for SD or melatonin induced gonadal regression. As GnIH neuronal cell bodies exist in the DMH, GnIH may convey melatonin signals to GnRH neurons (Fig. 1; Kriegsfeld *et al.*, 2015).

Ubuka *et al.* (2012) investigated how GnIH mRNA expression and GnIH neuronal activity are regulated by photoperiod and melatonin to investigate if GnIH conveys melatonin signals to GnRH neurons in Siberian hamsters. GnIH mRNA expression was higher in LD compared with SD. GnIH mRNA expression was also high in SD plus pinealectomized animals, and this

Table 1 Photoperiodic changes in neuroendocrine and endocrine signaling molecules in sheep, Syrian and Siberian hamsters

Dopamine	↑	↓	—	—	—	—
E2, T	↓	↑	↑	↓	↑	↓
Reproductive activity	↓	↑	↑	↓	↑	↓

high expression of GnIH mRNA is suppressed by melatonin. GnIH neuronal fiber density was also higher in LD and SD plus pinealectomized hamsters than LD plus melatonin or SD animals (Table 1). GnIH neuronal fibers extended to GnRH neurons and GnRH neurons expressed GnIH receptor. GnIH neuronal fiber terminals on GnRH neurons also increased in LD and decreased in SD. GnIH administration to the brain inhibited LH concentration in LD but increased LH concentration in SD. These results suggest that GnIH fine tunes LH levels through GnIH receptor expressed in GnRH neurons in an opposing fashion across seasons in Siberian hamsters (Ubuka *et al.*, 2012).

In transition from SD to LD, short duration of melatonin secretion may stimulate TSH synthesis in the PT, and TSH is transported to the hypothalamus to stimulate the conversion of T_4 to T_3 by inducing Dio2 expression in the hypothalamus of Syrian hamsters (Table 1). Although Dio3 is undetectable in both photoperiods in Syrian hamsters, changes in Dio3 was suggested to be important in Siberian hamsters (Table 1; Weems *et al.*, 2015).

Klosen *et al.* (2013) treated SD male Syrian and Siberian hamsters with a chronic central infusion of TSH. In both hamster species, TSH restored testicular activity. GnIH neuronal number was high in LD and TSH treated SD hamsters. Number of kisspeptin neurons in the Arc was significantly higher in LD than SD in Syrian hamsters but it was opposite in Siberian hamsters (Table 1). TSH was able to increase the number of kisspeptin neurons in the Arc in SD Syrian hamsters, whereas it reduced the numbers of kisspeptin neurons in the Arc to its LD level in SD Siberian hamsters (Table 1; Klosen *et al.*, 2013).

Conclusions

The mechanism to detect light-dark information in the eye and translate it into melatonin secretion from the pineal gland is the same among sheep, Syrian and Siberian hamsters (Fig. 1). Melatonin is secreted only during night either in diurnal and nocturnal animals or LD and SD breeders. Hypothalamic neuropeptides such as GnRH, GnIH and kisspeptin regulate gonadotropin secretion from the anterior pituitary gland, which regulate gonadal development and maintenance (Fig. 1). Therefore, photoperiodic reproductive activities depend on how GnRH, GnIH or kisspeptin neurons read melatonin concentration in the hypothalamus. There is also a mechanism of negative feedback of gonadal steroids to the hypothalamus to adjust gonadotropin secretion from the anterior pituitary gland. Sheep have developed an intricate mechanism to decrease GnRH pulse frequency by arcuate dopamine and kisspeptin neurons in non-breeding season (Fig. 1; Table 1). In sheep, photoperiodic information is conveyed to GnRH neurons by opposite changes in inhibitory GnIH expression and synchronized changes in stimulatory T_3 concentration according to duration of melatonin secretion (Table 1). Photoperiodic information is also conveyed to GnRH neurons by changes in GnIH expression and T_3 concentration in hamsters but changes in GnIH and GnRH neuronal activities synchronize in LD and SD (Table 1). This synchronization of GnIH and GnRH neuronal activities may be because GnIH has both inhibitory and stimulatory effects on gonadotropin secretion in hamsters and GnIH finetunes the activity of GnRH neurons according to season. In conclusion, changes in the direction of melatonin, TSH, T_3 , GnIH in LD and SD are the same among sheep, Syrian and Siberian hamsters, but GnRH, E2 or testosterone are activated in SD in sheep, short day breeder, but LD in hamsters, long day breeder. The primary roles of dopamine and kisspeptin neurons in the arcuate nucleus are to finetune pulsatile secretion of GnRH according to E2 or testosterone concentration instead of reading duration of melatonin secretion.

SNP	Single nucleotide polymorphism
T-ALL	T-lymphoblastic leukemia
TCR	T-cell receptor
TdT	Terminal deoxynucleotidyl transferase
TK	Tyrosine kinase
TKI	Tyrosine kinase inhibitor
TMPT	Thiopurine methyltransferase
WBC	White blood cells
WHO	World Health Organization

Definition and Classification

Acute lymphocytic leukemia (also called acute lymphoblastic leukemia; ALL) is a neoplasm of immature B- or T-cells (lymphoblasts). In the most recent World Health Organization (WHO) classification of hematopoietic and lymphoid tumors, it is classified under “precursor B-cell lymphoblastic leukemia/lymphoma” and “precursor T-cell lymphoblastic leukemia/lymphoma.” This classification has replaced the French–American–British (FAB) histopathologic classification of acute leukemia, originally proposed in 1976, which classified ALL into three entities: adult, childhood, and Burkitt type ALL. The new WHO classification system takes into account not only morphological and cytochemical characteristics of the disease but also its cytogenetic and clinical diversity. All in all, the widely used term “ALL” encompasses several entities as classified by WHO, defined below.

B-lymphoblastic leukemia (B-ALL) not otherwise specified (NOS; ICD-O code: 9811/3) is a neoplasm of precursor lymphoid cells committed to the B-cell lineage, typically composed of small to medium-size blast cells with scant cytoplasm, moderately condensed to dispersed chromatin and inconspicuous nucleoli, involving bone marrow and blood. By convention, the term B-lymphoblastic lymphoma (B-LBL), which is included under the same ICD-O code, is used when a process is confined to a mass lesion with no or minimal evidence of blood and bone marrow involvement (generally defined as less than 20% of lymphoblasts in the marrow). The term B-ALL does not encompass Burkitt leukemia/lymphoma.

B-ALLs with specific recurrent genetic abnormalities associated with particular clinical and phenotypic features, and/or of prognostic significance are classified as separate entities. These are as follows:

B lymphoblastic leukemia with $t(9;22)(q34;q11.2)$; *BCR-ABL1* (ICD-O code: 9812/3)

B lymphoblastic leukemia with $t(v;11q23)$; *MLL* (also called *KMT2A* or *MLL1*) rearranged (9813/3)

B lymphoblastic leukemia with $t(12;21)(p13;q22)$; *TEL-AML1* (*ETV6-RUNX1*) (9814/3)

B lymphoblastic leukemia with hyperdiploidy (9815/3)

B lymphoblastic leukemia with hypodiploidy (Hypodiploid ALL; 9816/3)

B lymphoblastic leukemia with $t(5;14)(q31;q32)$; *IL3-IGH* (9817/3)

B lymphoblastic leukemia with $t(1;19)(q23;p13.3)$; *E2A-PBX1* (*TCF3-PBX1*) (9818/3)

B lymphoblastic leukemia, *BCR-ABL1*-like (9819/3)

Additionally, B lymphoblastic leukemia with *iAMP21* has been depicted as a provisional entity with no separate ICD-O code (it is coded under B-ALL, NOS; ICD-O code: 9811/3).

T-lymphoblastic leukemia (T-ALL) is a neoplasm of precursor lymphoid cells with the same cellular characteristics as B-ALL but concerning precursor cells committed to the T-cell lineage.

Presentation and Diagnosis

The symptoms of ALL are usually nonspecific and may appear only weeks or even days before diagnosis. Fatigue and weakness are among the most common nonspecific symptoms. Fever, with or without night sweats, and weight loss are frequent. The cause of fever is often not found, although granulocytopenia may lead to rapidly progressing and potentially life-threatening bacterial infections. Many patients present with thrombocytopenia and/or neutropenia, easy bruising and/or bleeding (bleeding gums, epistaxis, purplish patches in the skin or petechiae), and anemia as a result of bone marrow failure and disrupted hematopoiesis. Dyspnea, chest pain, and dizziness may also occur. Bone and joint pain due to bone marrow and periosteal infiltration is frequent in children in whom it may be the only presenting symptom. Headaches, vomiting, irritability, cranial nerve palsies, seizures, papilledema, and blurred vision are manifestations of the central nervous system (CNS) involvement and/or leukemic meningitis but initial CNS involvement is uncommon.

A sensation of abdominal fullness and/or discomfort may appear due to hepatomegaly and/or splenomegaly. Hepatomegaly, splenomegaly, and lymphadenopathy at physical examination are found in about 20% of all patients and in approximately 50% of adult ALL presentations. Extramedullary infiltration may also lead to leukemia cutis (a raised, nonpruritic rash). Oliguria may occur as a result of dehydration, uric acid nephropathy, or disseminated intravascular coagulation (DIC).

The initial workup includes complete blood count (CBC) with peripheral blood smear, blood chemistry profile, liver and kidney function tests, coagulation analysis (including measurement of prothrombin time, partial thromboplastin time, and fibrinogen), and a tumor lysis syndrome panel (including measurement of serum lactate dehydrogenase (LDH), potassium, uricemia, calcium, and phosphorus). Computed tomography (CT) scans of the neck, chest, abdomen, and pelvis are recommended for detecting possible organ involvement, lymphadenopathy, and organomegaly. If any extramedullary involvement is suspected, a positron emission tomography (PET)/CT is used for diagnosis.

The leukocyte count in ALL patients may be elevated (majority of cases), normal, or decreased. T-ALL patients typically present with a high leukocyte count and often with a large mediastinal mass or other tissue mass. Circulating blast cells are present in virtually all cases. However, the percentage may be very low in some patients.

ALL diagnosis is based on a hematopathological evaluation of bone marrow aspirate and biopsy material, with a demonstration of at least 20% of bone marrow lymphoblasts confirming a definitive ALL diagnosis. According to the guidelines of the US National Comprehensive Cancer Network (NCCN), the diagnostic workup should include a morphologic assessment of Wright/Giemsa-stained bone marrow aspirate smears and of hematoxylin-and-eosin-stained bone marrow core biopsy and clot sections, a comprehensive immunophenotyping using flow cytometry, and a baseline characterization of the leukemic clone(s) (see “Pathology and Genetics” section for more) to facilitate subsequent analysis of the minimal residual disease (MRD). For the

latter, cytogenetic testing by fluorescence in situ hybridization (FISH) with a panel of the acute leukemia probes and reverse-transcriptase polymerase chain reaction (RT-PCR) for *BCR-ABL1* fusions (and other fusions in case of *BCR-ABL1* negativity), including determining the transcript size, are commonly used. In cases of aneuploidy, array comparative genomic hybridization (CGH) may also be useful.

Epidemiology and Risk Factors

Burden

ALL is mainly a childhood disease, with 75% of cases diagnosed in children under 6 years of age. It is also the most common form of childhood leukemia, accounting for 75%–80% of all childhood leukemia cases, while it accounts for only 20% of cases in adults. The estimated annual incidence worldwide is 1–4.8 cases per 100,000 population. In the United States, the age-adjusted incidence rate of all ALL is 1.58 per 100,000 population per year, with approximately 5970 new cases and 1440 deaths estimated in 2017. The prevalence of specific B-ALL types and of T-ALL is summarized in Table 1.

Etiology and Risk Factors

The etiology of both B- and T-ALL is not well known. However, some environmental exposures have been associated with an increased risk. Radiation is a well-documented leukemogenic factor in humans, with a direct relationship between cumulative radiation dose and the incidence of some leukemia types. ALL may develop following exposure to ionizing radiation as well as radiotherapy. Also chemotherapy has been associated with an increased risk of developing the disease. Moreover, some chemicals, like benzene and toluene, contribute to the risk of acute leukemias, including ALL, likely by mutating or ablating the bone marrow stem cells. Acute leukemia usually develops 1–5 years after exposure and is often preceded by bone marrow hypoplasia, dysplasia, and pancytopenia. Age over 70 years is also a known risk factor for ALL.

Moreover, several hereditary conditions are associated with an increased risk of ALL, in particular Down syndrome but also less frequent disorders: neurofibromatosis type 1, Bloom syndrome, Klinefelter syndrome, Schwachman–Diamond syndrome, Fanconi anemia, and ataxia telangiectasia.

Genome-wide association studies have identified several single nucleotide polymorphisms (SNPs) associated with an increased risk of B-ALL, including in *GATA2*, *ARID5B*, *IKZF1*, *CEBPE*, and *CDKN2A*. In true familial ALL cases, even though rare, mutations in *PAX5*, *ETV6*, and *TP53* have been described.

Pathology and Genetics

In smear preparations, B-ALL lymphoblasts present variably, from small blasts with scant cytoplasm, condensed nuclear chromatin and indistinct nucleoli to larger cells with moderate amounts of light-blue to bluish-grey cytoplasm, sometimes vacuolated, dispersed chromatin and multiple variably prominent nucleoli. Nuclei are round or convoluted. Coarse azurophilic granules are present in some lymphoblasts in about 10% of cases. In bone marrow specimens, B-ALL lymphoblasts have a relatively uniform appearance, with round or oval, indented or convoluted nuclei. Nuclei range from inconspicuous to prominent, the chromatin is finely dispersed and the number of mitotic figures varies. Lymphoblasts in B-ALLs with specific genetic abnormalities usually do not have any specific morphological or cytochemical features that would allow a more specific diagnosis. Also T-ALL lymphoblasts are morphologically indistinguishable from B-ALL lymphoblasts.

Table 1 The prevalence of different acute lymphoblastic leukemia (ALL) entities

Entity	Epidemiology
B-ALL with t(9;22)(q34;q11.2); <i>BCR-ABL1</i>	More common in adults (25% of all adult ALLs) than in children (2%–4%)
B-ALL with t(1;11q23); <i>MLL</i> rearranged	The most common leukemia in infants under 1 year of age; less common in older children; incidence increases with age into adulthood
B-ALL with t(12;21)(p13;q22); <i>TEL-AML1 (ETV6-RUNX1)</i>	Common in children (25% of all B-ALLs in children) but not seen in infants; incidence decreases with age (this entity is uncommon in adults)
B-ALL with hyperdiploidy	Common in children (25% of all B-ALLs in children) but not seen in infants; incidence decreases with age; accounts for 7%–8% of adult B-ALL cases
B-ALL with hypodiploidy	1%–5% of cases, both adults and children (nearly-haploid ALL likely in children only)
B-ALL with t(5;14)(q31;q32); <i>IL3-IGH</i>	Less than 1% of all ALL cases, both adults and children
B-ALL with t(1;19)(q23;p13.3); <i>E2A-PBX1 (TCF3-PBX1)</i>	About 6% of childhood B-ALL cases, uncommon in adults
B-ALL, <i>BCR-ABL1</i> -like	10%–25% of all ALL cases; incidence increases with age
B-ALL with <i>iAMP21</i>	About 2% of ALL cases in children; no data on the incidence in adults
T-ALL	About 15% of childhood ALL cases (more common in adolescents than in younger children) and 25% of adult ALL cases; more common in males than in females

B-ALL, B-lymphoblastic leukemia; T-ALL, T-lymphoblastic leukemia.

B-ALL lymphoblasts are nearly always positive for the B-cell markers CD19, cCD79a, and cCD22. None of these molecules on its own is a specific diagnostic marker but their combination or high intensity strongly supports the B-ALL diagnosis. In most cases, the expression of CD10, surface CD22, CD24, PAX5, and terminal deoxynucleotidyl transferase (TdT) is also found. The myeloid-associated markers CD13 and CD33 may be expressed and this does not exclude the B-ALL diagnosis. The PAX5 expression is considered to be the most specific and sensitive marker for the B-cell lineage in tissue sections but it is also expressed in some variants of acute myeloid leukemia. The expression profile of cell surface markers within the B-cell lineage varies with the B-cell differentiation (maturation stage). The immunophenotypes characterizing B-ALLs with specific recurrent genetic aberrations are summarized in Table 2.

T-ALL lymphoblasts are usually positive for TdT and variably express CD1a, CD2–CD5, CD7, and CD8, with CD3 (cytoplasmic) and CD7 being positive most frequently. Only CD3, however, is specific for the T-lineage. CD4/CD8 coexpression is common but it is not specific to T-ALL. TdT expression combined with that of CD34, CD1a, and CD99 may help to establish the precursor nature of T-lymphoblasts. CD52 may be expressed in 30%–50% of adult T-ALL cases. One or both of the myeloid markers may also be expressed but, like for B-ALL, this does not exclude the T-ALL diagnosis. Moreover, many markers characteristic for premature T-cells (e.g., CD2 or CD7) may also be expressed by immature natural killer (NK) cells. Therefore, it may be very difficult to distinguish the true NK-cell ALL (which is rare) and T-ALL associated with the expression of immature T-cell markers.

Clonal rearrangements of the *immunoglobulin heavy* locus (*IGH*) gene and rearrangements of the *T-cell receptor* (*TCR*) gene are found in both B-ALL and T-ALL, albeit at different frequencies. In B-ALL, *IGH* clonal rearrangements are found in nearly all cases and *TCR* rearrangements in up to 70% of cases, whereas in T-ALL, clonal *TCR* rearrangements are seen in most cases and simultaneous *IGH* rearrangements in about 20%.

Moreover, cytogenetic abnormalities are seen in a majority of B-ALL cases, many of them defining specific entities with unique phenotypic and prognostic features (Table 2). In addition to those “classifying” aberrations, deletions of chromosome 6q, 9p, and 12p are frequent in B-ALL but they do not seem to impact prognosis. Some other abnormalities observed in B-ALL may emerge as having some clinical utility. For example, the rare $(17;19)(q22;p13.3)$ translocation is associated with a very poor prognosis but there are too few cases to validate this alteration as a prognostic marker and classify these B-ALL cases as a separate entity.

In T-ALL, abnormal karyotype is found in 50%–70% of cases. The most common recurrent cytogenetic abnormality involves the *alpha* and *delta* *TCR* loci (14q11.2) as well as the *beta* (7q34) and *gamma* locus (7p14.1), with a multitude of partner genes, most common of them being the *TLX1* (also called *HOX11*; 10q24.3) and *TLX3* (*HOX11L2*; 5q35.1) transcription factors. The most prevalent deletions are those of chromosome 9p, encompassing the locus of the *CDKN2A* gene.

Alterations at a gene level are also found in ALL. In particular, a large number of recurrent genetic alterations (copy number alterations and specific intragenic mutations) are found in B-ALL. Many of them, such as those in the *PAX5* gene, are found in most of the subtypes, suggesting that they play a fundamental role in leukemogenesis. Others, like those in *RAS* and *IKZF1*, tend to be associated with specific subtypes (Table 2). In T-ALL, the most frequently mutated gene is *NOTCH1* which encodes a protein critical for early T-cell development (mutated in 50% of cases). In 30% of cases, mutations in *FBXW7*, a negative regulator of *NOTCH1*, are found. According to data in the Cosmic database, the genes that are most frequently mutated in ALL are the following: *IKZF1* (35% of cases), *ABL1* (21%), *NRAS* (10%), *TP53* (10%), *CDKN2A*, *PAX5*, and *KMT2D* (9% each). However, the data do not distinguish between B-ALL and T-ALL, which—given remarkable differences between the subtypes—is a serious limitation.

Management and Therapy

The introduction of new therapies has resulted in a dramatic improvement of cure rates, in particular in B-ALL patients. ALL has a relatively good prognosis in children (5-year survival rates up to 89%). However, the prognosis for adults remains less favorable, especially for those of older age.

Risk assessment in ALL is an essential part of treatment planning and the criteria, widely debated, have been evolving. Patient age, initial white blood cells (WBC) count, disease subtype, presence of CNS disease, and rapidity of response to induction therapy are recognized as important factors in assessing prognosis. For years, clinicians used to stratify children, adolescents, and young adults (AYA) with ALL into two groups: standard risk and high risk, based mainly on age, WBC count, and disease subtype. The Children’s Oncology Group (COG) has refined risk assessment criteria, creating four groups: very high, high, standard, and low risk. The very high risk category comprises all B-ALL patients with the $t(9;22)$ translocation (Ph-positive ALL) and/or presence of the BCR-ABL1 fusion protein, B-ALL patients with hypodiploidy (defined as less than 44 chromosomes), BCR-ABL1-like, or *iAMP21* subtype, and those with *KMT2A* alterations or failure to achieve remission with induction therapy, regardless of age and WBC count. About 4% of nonadult B-ALL patients fall into this category. Risk stratification for T-ALL has been more difficult and this entity is frequently categorized as very high risk. However, newer treatments have resulted in improved outcomes also for T-ALL patients. According to the current NCCN guidelines, the initial risk stratification of all ALL patients should be based on the presence of the $t(9;22)$ chromosomal translocation and/or BCR-ABL fusion protein (Ph-positive versus Ph-negative). Further stratification may be based on patient age, WBC count, comorbidities, and the presence of minimal residual disease (MRD).

The treatment of ALL is extremely complex, with treatment regimens, selection of drugs, doses, and schedules which differ according to the age group of patients (children, AYA, or older adults), risk stratification, and ALL subtype. However, all treatment protocols follow the same basic principles, with three main treatment phases: induction, consolidation, and maintenance. CNS prophylactic and/or therapeutic treatment is also a mandatory element of ALL management.

Table 2 The genetic and immunophenotypic profiles of different B-lymphoblastic leukemia (B-ALL) entities as well as their clinical significance

Entity	Genetic profile	Immunophenotype	Prognosis and predictive factors
B-ALL with $t(9;22)(q34;q11.2)$; <i>BCR-ABL1</i>	The $t(9;22)$ translocation resulting from fusion of <i>BCR</i> at 22q11.2 and <i>ABL1</i> at 9q34.1, with production of a BCR-ABL1 fusion protein (p190 BCR-ABL1 in most childhood cases and in about half of adult cases); the resulting aberrant chromosome 22 harboring the fusion <i>BCR-ABL1</i> gene locus is called Philadelphia (Ph) chromosome	Typically positive for CD10, CD19, and TdT, and negative for CD117 (KIT); CD25 expression highly associated with this entity, especially in adults; myeloid-associated markers CD13 and CD33 frequently expressed; T-cell precursor phenotype in rare cases	The worst prognosis of all types, particularly in adults; patients potentially responsive to tyrosine kinase inhibitors (e.g. imatinib), so prognosis may change with the introduction of targeted therapies
B-ALL with $t(v;11q23)$; <i>MLL</i> rearranged	Fusions of the <i>KMT2A (MLL)</i> gene with multiple genes (over 100 identified fusion partners), the most common partner being <i>AFF1 (AFF4; 4q21)</i> , followed by <i>MLLT1</i> (19p13.3), and <i>MLLT3</i> (9p21.3); none of these fusions is specific to this entity; frequent overexpression of <i>FTL3</i> ; very few additional mutations in infants, usually in the RAS pathway	Typically positive for CD19 and CD15, and negative for CD10 and CD24; the NG2 homolog usually expressed and relatively specific	<i>KMT2A-FFA1</i> translocation associated with a very poor prognosis, particularly in infants under the age of 6 months
B-ALL with $t(12;21)(p13;q22)$; <i>TEL-AML1 (ETV6-RUNX1)</i>	The <i>ETV6-RUNX1</i> translocation with production of the fusion protein (a putative negative regulator of the transcription factor RUNX1), likely an early event in the leukemogenesis	Positive for CD10 and CD19, and usually also for CD34; characteristic nearly complete absence of CD9, CD20, and CD66c (relatively specific); myeloid-associated markers, especially CD13, frequently expressed	Very favorable prognosis (cure in >90% of childhood cases); relapses later than for other B-ALL types
B-ALL with hyperdiploidy	Increased chromosome number (usually without structural aberrations), most commonly extra copies of chromosome 21, X, 14, and 4; the least common: chromosome 2 and 3	Positive for CD10 and CD19, and other typical B-ALL markers; most cases positive for CD34 and negative for CD45	Very favorable prognosis in children (cure in >90% of cases); not enough data for adults; trisomies may have more significance as prognostic factors than the actual number of chromosomes; simultaneous trisomy of chromosome 4 and 10 being associated with the best prognosis
B-ALL with hypodiploidy	Loss of one or more chromosomes and nonspecific structural aberrations in the other chromosomes (rare in near-haploid cases)	Typically positive for CD10 and CD19 but no other distinct features	Poor prognosis (likely even without MRD); the worst prognosis for nearly-haploid cases suggested by some studies
B-ALL with $t(5;14)(q31;q32)$; <i>IL3-IGH</i>	A functional rearrangement between <i>IL3</i> (chromosome 5) and <i>IDH</i> (chromosome 14) leading to constitutional overexpression of IL3 and eosinophilia	Typically positive for CD10 and CD19; even small numbers of blasts expressing these two markers in a patient with eosinophilia strongly suggests this diagnosis	No data
B-ALL with $t(1;19)(q23;p13.3)$; <i>E2A-PBX1 (TCF3-PBX1)</i>	<i>TCF3-PBX</i> translocation with production of the fusion protein (oncogenic); the fusion gene is located on chromosome 19, may be associated with loss of chromosome 1 (unbalanced translocation); an alternative <i>TCF3</i> translocation involving the <i>HLF</i> gene (chromosome 17) in rare cases	Typically positive for CD10, CD19, and cytoplasmic mu heavy chain (pre-B phenotype); typical strong expression of CD9 with lack or very limited expression of CD34 (with these features, this diagnosis may be suspected even if cytoplasmic mu is undetermined)	The <i>TCF3</i> translocation associated with very poor prognosis; possibly an increased risk of CNS relapses in patients with this entity
B-ALL, <i>BCR-ABL1</i> -like	Various chromosomal rearrangements of multiple genes with various partners; <i>CRLF2</i> rearrangements in approximately half of the cases; the tyrosine kinase-type translocations often involve <i>ABL1</i> with partners other than <i>BCR</i> , as well as other kinases; additionally frequent deletions and point mutations in other genes, particularly <i>IKZF1</i> (not specific to this entity) and <i>CDKNA2A/B</i> ; mutations in <i>JAK1</i> or <i>JAK2</i> found in about a half of cases with <i>CRLF2</i> rearrangements	Typically positive for CD10 and CD19; very high levels of the translocated <i>CRLF2</i> gene product (detectable by flow cytometry) in a subset of cases with these translocations	Overall poor prognosis; this may be due to an increased risk of MRD (controversial); children resistant to induction therapy usually have a translocation involving <i>PDGFRB</i> (most often with <i>EBF1</i>) and are very responsive to ABL-class tyrosine kinase inhibitors (e.g. imatinib or dasatinib); patients with <i>JAK</i> mutations or translocations may be candidates for treatment with JAK inhibitors (to be tested)
B-ALL with <i>iAMP21</i>	Intrachromosomal amplification of chromosome 21 (<i>iAMP21</i>) detectable with FISH probes recognizing the <i>ETV6-RUNX1</i> translocation; multiple other chromosomal abnormalities (most commonly involving chromosome X and 7) in 80% of cases; deletions of <i>RB1</i> and <i>ETV6</i> as well as <i>CRLF2</i> rearrangements more frequent than in other ALLs	Unknown	Unclear

The goal of the induction therapy, the first phase of the ALL treatment, is to reduce tumor burden by clearing as many leukemic cells as possible from the bone marrow, that is to induce remission. Most inductions regimens are based on a combination of vincristine, anthracycline (e.g., daunorubicin or doxorubicin, in particular for higher risk patients), and a corticosteroid (e.g., dexamethasone or prednisone) with or without L-asparaginase and/or cyclophosphamide, given over the course of 4–6 weeks. An alternative is the so-called Hyper-CVAD regimen which alternates cycles of hyperfractionated cyclophosphamide, vincristine, doxorubicin (adriamycin), and dexamethasone with those of high-dose methotrexate and cytarabine.

Most children achieve complete remission (CR) within 4 weeks of the induction therapy. If CR is not achieved within 6 weeks, alternative treatments are started. In adults, a regimen based on a combination vincristine/prednisone/anthracycline is associated with 75% CR rates. Dexamethasone has been shown to give better outcomes compared to prednisone. It has a better penetration into the CNS, which explains its efficacy in preventing CNS relapse. However, it is associated with severe toxicities and its advantage for the overall survival has yet to be demonstrated.

CNS prophylaxis after induction chemotherapy aims at preventing CNS disease or early CNS relapse. The CNS is the initial site of ALL relapse in more than half of children unless prophylaxis is given and it is also a frequent site of relapse in adults. The goal of CNS prophylaxis and/or treatment is to clear leukemic cells within sites that cannot be easily accessed with systemic chemotherapy because of the blood–brain barrier. Different regimens of CNS-directed therapy exist. Many authorities recommend intrathecal methotrexate, often combined with cranial irradiation. Triple intrathecal therapy (methotrexate, hydrocortisone, cytarabine), with or without high-dose systemic chemotherapy (e.g., methotrexate or cytarabine), may substitute for cranial irradiation which can lead to late intellectual disabilities when used in children. For adults, prophylactic intrathecal chemotherapy alone is considered sufficient. CNS prophylaxis is typically administered to all patients throughout the entire course of ALL therapy.

The consolidation treatment aims at eliminating any leukemic cells remaining after induction therapy, further eradicating residual disease. The postremission induction phase of treatment may also be referred to as intensification therapy. It typically involves an intensive multidrug regimen. A variety of regimens are used in different centers and trials, although frequently containing similar drug combinations to those that were used during the induction treatment. High-dose methotrexate, cytarabine, 6-mercaptopurine (6-MP), cyclophosphamide, vincristine, corticosteroids, and L-asparaginase are frequently incorporated into consolidation/intensification regimens. For treatment of younger children, adjusted doses and frequencies are used.

Maintenance therapy aims to prevent disease relapse after postremission induction and consolidation therapy. Most regimens are based on daily 6-MP and weekly methotrexate, typically with a periodic addition of vincristine and corticosteroids, for 2–3 years. Of note, the efficacy of the maintenance therapy is determined by the metabolism of 6-MP. In particular, the efficacy of the active metabolite production is modified by polymorphisms in thiopurine methyltransferase (TMPT). Genotyping TMPT allows to anticipate decreased bioavailability or increased toxicity of 6-MP and adjust the dose. The optimal duration of the maintenance therapy is not clearly defined and the therapy is frequently stopped due to associated toxic effects.

The emergence of targeted drugs offers hope for more effective treatments of ALL. In particular, adding tyrosine kinase inhibitors (TKIs) to the induction treatment regimens of Ph-positive ALL patients has significantly improved their prognosis. Imatinib (also called imatinib mesylate; brand name: Gleevec®, Novartis Pharmaceuticals), an inhibitor of the BCR-ABL tyrosine kinase, has been approved by the US Food and Drug Administration (FDA) for treatment of relapsed or refractory Ph-positive ALL adult patients and of all untreated Ph-positive pediatric patients. Dasatinib, a second-generation TKI which inhibits both the BCR-ABL tyrosine kinase and kinases of the Src family, seems to be even more effective than imatinib due to its capacity to inhibit several TK-related signaling pathways. It has also been shown to maintain activity against cells harboring several (but not all) ABL domain mutations which confer resistance to imatinib. Furthermore, it has a better penetration of the blood–brain barrier and so it may prove useful in the CNS prophylaxis. Dasatinib (under the brand name of SPRYCEL, Bristol-Myers Squibb Co) has been approved by FDA for treatment of pediatric patients with Ph-positive chronic myeloid leukemia and it is being extensively trialed (phase II and III) for treatment of ALL. Single-agent TKI therapy in Ph-positive ALL patients has been shown to yield improved response to induction therapy as compared to chemotherapy. However, the remission-free periods are relatively short for both imatinib and dasatinib alone. TKIs have been shown to provide most benefit, with significantly improved disease-free and overall survival rates, when combined with corticosteroids. Patients with CD20-positive B-ALL benefit from the addition of rituximab, an anti-CD20 monoclonal antibody, to standard ALL chemotherapy regimens. All these agents may be incorporated as part of the induction, consolidation, and/or maintenance therapy in the initial treatment of ALL, or in regimens for treating relapsed and/or refractory disease.

Allogeneic hematopoietic stem cell transplantation (HSCT) used to be considered the standard of care in AYA and adults with Ph-positive ALL, and for relapsing ALL patients. However, with the advent of BCR-ABL-targeted TKIs, its role has been questioned. Still, it may offer some benefit to specific groups of Ph-positive patients who relapse after initial remission.

Treatment of relapsed ALL remains a challenge. Combining standard chemotherapy regimens with emerging targeted drugs offers much hope to this effect. In particular, mitoxantrone (Novantrone®, Immunex Corporation; an anthracycline derivative), cytarabine, fludarabine/cytarabine/granulocyte colony-stimulating factor/idarubicin (FLAG-IDA), methotrexate/asparaginase (CAPIZZI), and blinatumomab (a monoclonal antibody against CD19 and CD3) have been shown to provide benefit to patients with CD19-positive ALL, while inotuzumab ozagamicin (FDA-approved since August 2017) has been shown to be useful in patients with CD22-positive disease. Several first-, second-, and third-generation TKIs are being currently tested in clinical trials and their approval for treatment of relapsed/refractory ALL, and in particular for BCR-ABL1-like ALL, is likely just a matter of time. However, as of now, bone marrow transplant remains the only cure for relapsed/refractory ALL.

For patients who are not eligible for transplant, generation of chimeric antigen receptor T-cells (CAR-T) targeting specific molecules on the surface of cancer cells may be a solution. In August 2017, FDA approved the anti-CD19 CAR-T therapeutic

agent tisagenlecleucel (KYMRIA[®], Novartis Pharmaceuticals) for treatment of refractory or relapsed B-ALL patients (at least second relapse) below 25 years of age. However, CAR-T therapy is associated with severe potentially fatal toxicities (like cytokine release syndrome, B-cell aplasia, and cerebral edema) and its use should be preceded by a specific risk evaluation. FDA also requires a special certification for centers administering this therapy. For relapsed or refractory T-ALL, nelarabine, a purine nucleoside analog, is currently an approved treatment.

Assessing the response to treatment also remains a challenging issue. Complete remission (CR) is defined as the absence of circulating blasts and extramedullary disease. However, patients who achieved CR according to morphological assessment can potentially harbor leukemic cells in the bone marrow, giving rise to a low-level disease which is not detectable by conventional cytomorphological techniques (minimal residual disease, MRD). Many trials have confirmed that MRD is the strongest prognostic factor in both children and adults. Therefore, applying reliable sensitive methods to detect MRD is of utmost importance for further treatment planning and monitoring of treatment response at all stages following the induction therapy. MRD can be detected by multicolor flow cytometry or sensitive molecular techniques targeting characteristic genetic or chromosomal aberrations, like RT-PCR or next-generation sequencing.

Glossary

Critical day length (or critical night length) The length of the light (or dark) fraction of the light-dark cycle that separates a strong long-day response from a strong short-day response in the photoperiodic response curve.

Diapause A state of hormonally- and genetically-regulated developmental or reproductive arrest, accompanied by a major shutdown in metabolic activity.

Diapause syndrome Traits tightly linked with diapause.

Photoperiodic response curve The response of a population to a range of photoperiods.

Photoperiodism Biological ability to respond to photoperiod.

Quiescence A state of dormancy directly imposed by adverse environmental factors.

Nomenclature

CA Corpora allata

JH Juvenile hormone

Insects and Photoperiodism

Insects belong to the class Insecta within the subphylum Hexapoda, the Phylum Arthropoda. Insects are invertebrates with three body parts (head, thorax, and abdomen) and three pairs of jointed legs, and are the most diverse group of animals on this planet. There are more than a million described species of insects, which represent more than half of all known living organisms. This high species richness is attributed to several factors, one of which is their small body size. Most insects are 1–10 mm in body length, allowing these small organisms to inhabit many more niches in any given environment than that by large organisms. Their small size, however, also makes them vulnerable. Small organisms possess larger surface area to volume ratios than large organisms, making them highly susceptible to environmental changes as a result of heat-transfer across their body surface. Ectotherms such as insects are the most severely affected by environmental temperature changes.

Although the axis of the Earth is tilted by only 23.4° from the plane of its orbit around the sun, this is enough to provide the dramatic contrast between the heat of summer and the cold of winter. Because insects are limited in their abilities to regulate their own body temperature, they are at the mercy of seasonal temperature changes. It is, therefore, a necessity that insects anticipate arrival of the seasons by reading environmental cues so as to prepare physiologically and/or behaviorally. Such cues should be informative and reliable, and should predate the arrival of unfavorable conditions, i.e., temperatures. A highly indicative cue is *day length*. Numerous organisms, including insects, anticipate seasonal changes by monitoring day length, and may exhibit a biological response, known as *photoperiodism*, to these photoperiodic variations. *Temperature* is also a useful cue for timing periodic behaviors and triggering physiological changes that affect reproductive success. Temperature, however, can be unreliable due to large daily fluctuations and inter-annual variation, particularly in terrestrial environments (see [Goto and Numata, 2014](#)).

Photoperiodism was first demonstrated in plants nearly a century ago. Shortly thereafter, photoperiodism was described in animals in the first published report involving an insect, the strawberry root aphid *Aphis forbesi*. Today, photoperiodic responses have been recorded in many insect species, and insects that lack a photoperiodic response are considered to be exceptions, at least in temperate zones.

This overview presents a collection of the current knowledge of insect photoperiodism. Please take note: certain entries relate to the endocrine control of reproduction in insects and other organisms in this encyclopedia, and readers are referred to these specific sections for more detailed information.

Diapause

The most well-known photoperiodic response in insects is the photoperiodic regulation of *diapause*. Diapause is a state in which development or reproduction is suppressed or arrested, and is accompanied by a major shutdown in metabolic activity. Insects that are destined to enter diapause generally accumulate additional energy reserves prior to the onset of diapause. Sufficient

energy reserves and low metabolic activity give rise to a high probability of survival during and after adverse seasons. Unlike a simple *quiescence*, i.e., an immediate response at any stage to an unfavorable environmental condition, diapause is a genetically and hormonally programmed response. Some insects enter diapause at a particular stage in each generation regardless of the environmental conditions; this is referred to as *obligatory diapause*. The entry into diapause can be triggered by a number of factors, but is most frequently determined by environmental factors, and usually involves day length. This environmentally governed type of diapause is referred to as *facultative diapause*. Insects that enter diapause for overwintering (*winter diapause*) generally react to the shortening of day lengths, short day lengths, or to a change from long to short day lengths. These species are referred to as “*long-day species*”, analogous with plants. *Summer diapause* is also widespread, is induced by a long photoperiod, and is an inverse of winter diapause in many ways. Species that enter diapause in response to long photoperiods are referred to as “*short-day species*” (see Tauber *et al.*, 1986).

A selection of photoperiodic response curves found in insects is seen in Fig. 1. Each response curve consists of a series of points that represent the percentage of diapause individuals in a sample population reared at a specific day length. *The critical day length*, i.e., the length of the light fraction of the light-dark cycles that separates a strong long-day response from a strong short-day response in the photoperiodic response curve, is the representative value of the photoperiodic response. It is also noteworthy that slope of the photoperiodic response curve between photoperiods that elicit a short-day response and those that elicit a long-day response is usually quite sharp. This indicates that insects can measure a change of as little as 10–15 min in the length of the daily light period and this change may result in a significant change in the proportion of the population entering diapause (Saunders, 2002).

Diapause occurs at a specific stage (or at two or more stages in some cases) in each species. *Embryonic diapause* (i.e., diapause in the egg stage) is common in Lepidoptera and Hemiptera and in some Diptera species. *Larval diapause* is especially common in the lepidopterans and frequently occurs at the final instar, but is also known to occur at early instars. *Pupal diapause* is particularly common in Lepidoptera and Diptera orders and frequently occurs at the true pupal stage. *Adult diapause* is widespread in the Coleoptera, Hemiptera, Hymenoptera, Orthoptera, Neuroptera, Diptera and Lepidoptera orders. Embryonic, larval and pupal diapauses are characterized by *developmental arrest*, whereas adult diapause is characterized by *reproductive arrest* (*reproductive diapause*), i.e., the suppression of reproductive organ development.

Photoperiod frequently regulates diapause induction, but also regulates the maintenance and termination of diapause. Individuals that enter diapause can remain locked in developmental or reproductive arrest, even if environmental conditions are suitable. For example, in the lacewing *Chrysoperla carnea*, reproductive diapause is deep and not easily terminated when induced in early autumn, thereby avoiding an unfavorable termination of diapause before the onset of winter. The diapause termination

Fig. 1 A selection of photoperiodic response curves in long-day (A–D), intermediate (E) and short-day (F) species. Critical day length is also shown in (A). The responses under ultra-long and ultra-short photoperiods, which do not occur naturally, are generally quite variable among insect species.

process is regulated by photoperiod in some species. For example, reproductive diapause induced by short days is promptly terminated by exposure to long days in the bean bug *Riptortus pedestris*.

As a result of photoperiodic responses, insects are able to time their growth and reproduction to coincide with appropriate seasons, thereby influencing phenology, voltinism (the number of generations per year), and ultimately population growth (Denlinger, 2009).

Photoperiodic Regulation of Reproductive Traits

Reproductive diapause is the most common photoperiodic regulation of reproduction in insects. Both sexes enter diapause in many species. The ovaries of diapause females are small and the oocytes contain little or no yolk. The testes of males remain small during diapause in some species, but are well-developed and contain sperm in others. Development of the male accessory gland, i.e., the organ that produces spermatophores and factors responsible for sperm activation, is usually suppressed during diapause. Mating behavior is strongly suppressed during diapause. Mating takes place in spring after diapause termination in many species, but occurs in autumn before entering diapause or both in autumn and in spring in others. Sexual differences in the tendency to enter diapause have also been recorded, not only in adult diapause but also in diapause at other developmental stages. In some species, males are more likely to enter diapause than are females; however, the opposite tendency has also been observed. This sexual difference appears to reflect the energetic cost of diapause, wherein the overwintering sex has a significantly lower fecundity than its counterparts that developed directly. Extreme examples of sexual difference are found in mosquitoes, bees, and wasps. In these insects, only females enter diapause and overwinter, whereas males do not have the ability to enter diapause, and thus, die off before or during the unfavorable seasons.

The *photoperiod-sensitive stage* refers to the stage during which an insect receives the photoperiodic cues that trigger the photoperiodic response. In many species, the photoperiod-sensitive stage occurs far in advance of the actual diapause stage. The most extreme example of an “advanced” photoperiodic perception is when this sensitive stage occurs in one generation and the developmental arrest occurs in the next; i.e., *maternal effect*. This can be found in many parasitic wasps, higher Diptera, and some Lepidoptera species. The most classical example is seen in the silk moth *Bombyx mori*. Photoperiodic signals experienced by the embryos and larvae of one generation determine the developmental fate of the embryos of the next generation. In other cases, the mother influences the diapause fate of her progeny in their larval or pupal stages. Short day lengths influence female jewel wasps, *Nasonia vitripennis*, to produce eggs that are destined to enter diapause at the final larval instar. In this case, the progeny has no ability to respond to environmental factors to avoid diapause entry. In the blow fly *Lucilia sericata*, however, the progeny that is destined to enter diapause by maternal effect is still able to respond to environmental cues to avoid diapause entry. In this case, the progeny is able to integrate the information from the mother with the environmental information that they received so as to make a final decision to enter or avert diapause. Thus, mother insects are not only simply function in the production of offspring and in the embryonic development of her progeny, but are also able to initiate an effect that is expressed at a much later stage of development.

Seasonal parthenogenesis is found in aphids, in which there is a photoperiodic control of the mode of reproduction, namely, parthenogenetic and sexual reproduction. Most temperate species reproduce during the summer as a series of viviparous, parthenogenetic females (virginoparae), whereas they produce sexual forms (males and oviparae, i.e., females that are able to produce eggs) as the days become shorter in autumn. The fertilized oviparae deposit diapause eggs that overwinter. The viviparity and parthenogenetic reproduction of aphids promote rapid multiplication and allow for the maximum utilization of available resources during seasons that are suitable for population growth, whereas sexual reproduction allows for genetic recombination and production of a hibernating form of offspring, i.e., diapause progeny.

Photoperiodic Regulation of Other Traits

Photoperiod regulates not only reproductive traits but also other traits, such as stress tolerance, growth rate, seasonal morphs, behaviors, and migration, which can directly or indirectly contribute to reproductive success. Some of the traits are tightly linked with diapause, and thus, are components of diapause, i.e., the *diapause syndrome*, in some species, but not in others.

Insects that enter winter diapause require a degree of cold tolerance to survive severe winter conditions. In some cases, cold tolerance occurs as a diapause syndrome. In many insects, the rate of development is controlled by photoperiod. For example, the cricket *Modicogryllus siamensis* needs to molt 7 times over 45–55 days of long day lengths in order to emerge as an adult, whereas this species requires 10–13 molts over 65–145 days of short day lengths. This photoperiodic response prevents untimely adult emergence in an unfavorable season.

Seasonal morphs have been noted in Lepidoptera, Orthoptera, Hemiptera, and Thysanoptera, and in most cases photoperiod is the deciding environmental factor that is involved. One such good example has been observed in butterflies, whereby the long days of summer may favor the production of light-colored wings, which minimize overheating in the warm season, but, the short days of autumn may favor darkly pigmented wings, which increase the efficiency of the absorption of solar energy, and hence promote high activity and reproductive success. Color changes for camouflage are sometimes noted for diapause individuals. For example,

nondiapauses adults of the brown-winged green stink bug *Plautia stali* are green but turn brown when they enter diapause in autumn. When the bugs become reproductively active during the spring, they turn green again. Such color changes help the insect blend with the predominant colors of the environment. Photoperiodic regulation of alary dimorphism (dimorphism in wing form) and flight muscle degeneration are also widespread. Wing and flight muscles are particularly expensive to maintain, and thus, brachypterous morph and flight muscle degeneration can help save energy reserves that can otherwise be allocated to increase their chance of survival and reproductive success.

Although not mutually exclusive, migration and diapause are alternatives for insects to counteract changes in their environment. Insects may enter diapause in situ to withstand severe conditions or migrate to favorable areas; i.e., diapause entry is the temporal escape from the inimical environment, whereas migration is the spatial escape. The monarch butterfly, *Danaus plexippus*, is the classic model of the latter, and this species migrates to hibernation sites in autumn and returns to breeding and feeding areas in spring. Aphids also migrate from summer host plant species to winter one. Many of these migrations are components of diapause and are controlled by photoperiods.

Mechanisms Underlying Photoperiodic Responses

To show the photoperiodic response, insects must be equipped with a series of modules; i.e., photoreceptors, photoperiodic time measurement system, photoperiodic counter, and endocrine effectors (Fig. 2; Goto and Numata, 2014).

Fig. 2 Modules establishing photoperiodism, which regulate winter diapause at adult stage (reproductive diapause in the long-day species). Light/dark signals are received by photoreceptors for the photoperiodic time measurement system. The photoreceptors are retinal (the compound eyes) or extraretinal (the brain). The visual pigments are involved in this photoreception. The photoperiodic time measurement system measures the length of day or night and involves the circadian clock. The photoperiodic counter counts the number of photoperiodic cycles. When a hypothetical “diapause titer” exceeds an internal threshold, the activity of the corpora allata is suppressed and a short-day response (diapause) is induced. When the titer was at subthreshold level, the endocrine effectors actively synthesize and secrete hormone(s) for reproductive organ development. For further details, see in text discussions.

Photoreceptors

Insects possess three types of external photoreceptor organs, the *compound eyes*, *ocelli*, and *stemmata*. Compound eyes are primarily used for motion detection, ocelli are simple eyes found in immatures and adults, and stemmata are the visual receptors in larvae of many holometabolous insects. These organs follow the same basic structural plan: a lens to focus the light, light-sensitive cells, and axons from the photoreceptive cells projecting to the optic lobe of the brain. The usage of compound eyes and stemmata as photoperiodic photoreceptors has been reported in Hemiptera, Orthoptera, Lepidoptera, Coleoptera, and Diptera. Examples include *R. pedestris*, which uses the central part of the compound eyes for photoperiodic induction of adult diapause, and larvae of the carabid beetle *Leptocarabus kumagaii*, which use the stemmata for photoperiodic induction of larval diapause. Involvement of the ocelli in a photoperiodic response has not been demonstrated.

Involvement of the brain as the nonvisual extraretinal photoreceptor is also verified in Hemiptera, Orthoptera, Lepidoptera, Coleoptera, and Diptera. Notable examples include a photoperiodic induction of diapause in the hawkmoth *Manduca sexta*. In this species, short days in the larval stage induce pupal diapause, whereas diapause can be averted during long days. Brains attached with endocrine organs, corpora cardiaca and corpora allata (CA), were taken from the larvae and were cultured in vitro under long days or short days. The brains were implanted in recipient larvae that had been reared under a short day length regime. Brains that were cultured under long days altered the diapause program in some recipients, but the brains that were cultured under short days did not. These findings show that brains can receive photoperiodic information without retinal photoreceptors in vitro. The photoperiodic photoreceptor responsible for alteration of the reproductive modes in an aphid also lies in the brain. It is also important to note that retinal and extraretinal photoreception is not mutually exclusive. Usage of both types of photoreceptors has been demonstrated in adult diapause induction in *P. stali*.

Two types of photoreceptive molecules are known in animals: one is *visual pigments*, opsin proteins conjugated to vitamin A-based pigments retinal or 3-hydroxyretinal; and the other is *cryptochrome*, a cryptochrome protein conjugated to the vitamin B₂-based pigment flavin. Visual pigments are the major photoreceptive molecules in the retinal photoreceptors. Insect color vision is achieved with the presence of multiple types of visual pigments covering a broad range of wavelengths. Cryptochrome, which absorbs short wavelength light in the range from ultra-violet to blue, is well-known as a photoreceptor for resetting a circadian clock by phase delay or advance. The disruption of photoperiodic responses by the dietary vitamin A-deficient experiment in *B. mori* and other species, and by gene silencing of opsin expression in *M. siamensis* suggest an involvement of visual pigments in photoperiodic photoreception. The role of cryptochrome in photoperiodism has not been demonstrated.

Photoperiodic Time Measurement System

Although the term “day length,” i.e., the duration of the daily light phase, is commonly used to describe given photoperiodic conditions, most insects measure the *night length*, the duration of the daily dark phase, based on photoperiodic information acquired through photoreceptors. This information is processed by the *photoperiodic time measurement system*. Although time measurement is sometimes regarded as a simple qualitative or all-or-none mechanism, i.e., simple discrimination between short and long days, various experiments with many insect species have revealed that it is instead quantitative.

Erwin Bünning, a German chronobiologist, first proposed the involvement of a circadian clock in photoperiodic time measurement. In his hypothesis (the Bünning's hypothesis), a circadian clock with 24-h periodicity comprises two 12-h half-cycles (photophil and scotophil). Short-day effects are seen when light is restricted to the photophil, while long-day effects are produced when light penetrates the scotophil. Although this concept is too naïve to explain the range of photoperiodic responses in various insect species, the basic concept, i.e., involvement of a circadian clock in photoperiodic time measurement, is now widely accepted not only in insects but also in other organisms. A variety of photoperiodic time measurement models have been established by incorporating the data accrued under different experimental conditions; among these, the *external coincidence model* and *internal coincidence model* are highly influential. The external coincidence model is based on a circadian clock, which sets its phase and positions of the “photoinducible phase ((ϕ)i)” in the latter half of scotophase. Under short days, (ϕ)i is not illuminated by light, eliciting a short-day response; under long days, (ϕ)i is exposed to light and a long-day response is induced. The internal coincidence model proposes two oscillators entrained by dawn and dusk, respectively, and whose internal phase relationship changes with photophase length. Specific phases for each oscillator are active phases, and long-day responses occur when these overlap. The earliest attempts to model time measurement envisaged a non-repetitive *hourglass* timer that measures night length from the dusk signal of the daily cycle. This hourglass-timer concept is fascinating for insects that show little clear evidence for a role of the circadian system in photoperiodic time measurement.

Although for many years insect physiologists have focused on the time measurement system, functional elements involved in the system are still largely veiled. For further explanation on the photoperiodic time measurement models (see [Saunders, 2002](#)).

Photoperiodic Counter

Although a single inductive photoperiodic cycle is sufficient to promote a seasonal event in some species, such a case is quite rare. In most cases, a number of the inductive photoperiodic cycles are required to elicit a photoperiodic response. A *photoperiodic counter* counts the number of cycles during the photoperiod-sensitive period and compares the number (the induction sum) with an internal threshold, which triggers a physiological response mediated by endocrine effectors.

The experimental transfer of insects from long to short day cycles or vice versa can be used to determine the photoperiod-sensitive stage and also the number of inductive cycles required for photoperiodic induction (or termination). Both short days and long days can frequently be accumulated, but there are some examples of accumulation of either of them. In one model of photoperiodic summation (Gibb's model), insects accumulate or reduce (under short or long days, respectively) a hypothetical diapause titer in the counter system. The time measurement system may evaluate photoperiods quantitatively, and thus the accumulated diapause titer in each day may quantitatively differ among photoperiods. At the end of photoperiod-sensitive stage, insects compare the accumulated titer with the internal threshold. A short-day response is elicited upon exceeding the internal threshold, whereas a long-day response is induced at subthreshold values.

The counter model is largely conceptual at present, and therefore, biochemical and molecular biological dissection are eagerly awaited.

Endocrine Effectors

Various hormones such as the *juvenile hormones (JHs)*, *ecdysteroids*, *prothoracicotrophic hormone*, *insulin-like peptides*, and *diapause hormone* regulate induction, maintenance, and termination of diapause at each of developmental stages (Denlinger *et al.*, 2012). In this section, we focus only on hormones that regulate adult diapause.

The major role of JH, an acyclic sesquiterpenoid that is synthesized at and released from the CA, in adult diapause has been reported in a large number of insect species; high hemolymph titer of JH induces reproduction, whereas low JH titer induces adult diapause. The JH titer is regulated by both JH synthesis and the degradation of this hormone. Active suppression of the CA by the brain has been demonstrated during diapause in Coleoptera, Diptera, Hemiptera, and Orthoptera. Although the significance of the brain neurons which reside in pars lateralis and pars intercerebralis and that of neuropeptides in the brain and the corpora cardiaca for regulation of the CA are reported, specific neurons and molecules have not been identified in any insect. In the Colorado potato beetle, *Leptinotarsa decemlineata*, JH esterase, which degrades JH, plays a central role of regulating the JH titer in diapause-destined adults, while in the locusts there are no differences in JH esterase activity between long-day and short-day adults.

The role of ecdysteroids in the regulation of adult diapause has been mainly investigated in *Drosophila melanogaster*, although this arrest appears to be quiescence induced by low temperature, rather than photoperiod. Ecdysteroids are synthesized in the prothoracic gland in larval and pupal stages, and in the ovaries in the female adult stage. Ovaries produce low levels of ecdysteroids during this reproductive arrest, and injection of 20-hydroxyecdysone terminates the arrest in a dose-dependent manner. The significance of ecdysteroids in regulating adult diapause has been proposed in Diptera, Hemiptera, and Orthoptera.

The involvement of insulin signaling in adult diapause has recently received substantial attention, involving *D. melanogaster* and the mosquito, *Culex pipiens*. In both cases, reduced insulin signaling appears to be linked to adult diapause. In *C. pipiens*, the insulin signaling cascade appears to reside in upstream of the JH signaling pathway.

PUBERTY AND METAMORPHOSIS RELATED TO REPRODUCTION

Puberty in Fish

Eva Andersson, Geir L Taranger, and Anna Wargelius, Institute of Marine Research, Bergen, Norway

Rüdiger W Schulz, Utrecht University, Utrecht, The Netherlands

Introduction

Puberty is the transition from an immature juvenile to a mature, adult stage when an individual becomes capable of reproducing sexually for the first time. This involves the functional competence of the endocrine system that governs maturation in vertebrates; the brain-pituitary-gonad (BPG) axis. This axis is composed of neuro-endocrine circuits in the brain that regulate the synthesis and release of the two gonadotropins in the pituitary, follicle stimulating hormone (Fsh) and luteinizing hormone (Lh). The two gonadotropins regulate pubertal development and adult functioning of the gonads to ensure the production of hormones and growth factors required for the development and maturation of the germ cells. Gonadal hormones and growth factors also exert feedback effects on the brain/pituitary level, where the gonadal feedback is merged with information from other internal (e.g., nutritional or health status) and external (e.g., photoperiod, temperature, behavior of conspecifics) sources into an integrated output to control the synthesis and release of Fsh and Lh.

Among the regulatory systems operating in the brain to control the different aspects of reproduction there are a number of systems operating in parallel to regulate the release of Fsh and/or Lh. Examples include the kisspeptin-Gnrh system, the gonadotropin-inhibitory hormone (Gnih), the neurotransmitter dopamine, neuropeptide Y, or neurokinin. However, different from the situation in mammals, where the kisspeptin-Gnrh system clearly is the decisive gateway controlling the regulation of reproduction, this is not the case in fish (Liu *et al.*, 2017), where the above-mentioned set of parallel pathways apparently operate in a more balanced manner and can compensate for each other's activity.

The activities of these regulatory system converge onto the pituitary. Production, but in particular release, of Fsh and Lh is what determines pubertal development of the gonads. It is important to realize that different from land vertebrates, where the two gonadotropins are produced in a single cell type, while there are separate Fsh- and Lh-producing gonadotrope cells in fish. Here, we will focus on exogenous and endogenous factors that are integrated by the brain-pituitary system to modulate the pituitary gonadotropin release in such a way that puberty is either initiated or blocked, i.e., we will discuss conditions that influence the timing of puberty.

Puberty is a major lifecycle transition period, a prerequisite for vertebrate reproduction and thus the conservation of species. Studies of the physiological background determining the control of puberty in fish are highly relevant also from an applied point of view to provide efficient protocols for producing food for human consumption, as aquaculture accounts for around 50% of the global production of fish. The sustainability of aquaculture can be compromised by early (precocious) puberty, a major problem particularly in males in many farmed fish species. The compromise is largely due to negative effects on fish growth, health, and welfare. When puberty is reached before the fish reach harvestable size in aquaculture, the mobilization of energy and resources required for the development of the gonads, secondary sexual characters, and for reproduction-specific behaviors, drain energy for somatic tissues, thus impairing somatic growth and resulting in a higher feed demand to restore growth after completion of spawning. Many salmonids die after spawning, and hence are lost in terms of eatable product. Welfare issues are particularly relevant in several salmonid species that spend different periods of their lifecycle in either fresh or sea water, and where puberty is associated with a reduced capacity to survive in seawater, while the growth to harvest size takes place in sea water. Moreover, when fish escape from aquaculture facilities, the chance that they have a genetic impact on wild populations is much higher when the escapees are sexually mature. However, in other species, a delay or a complete failure to enter puberty can be a limiting factor for successful cultivation.

While important advances have been made regarding the control of final gonadal maturation, ovulation and spermiation under farming conditions, relatively few advances have been made regarding the control of puberty. Approaches to control puberty may imply techniques to delay/arrest, or to induce/advance puberty, according to the species-specific reproductive patterns shown under cultivation conditions.

Environmental Conditions Affect the Timing of Puberty

The reproductive cycle in those fish that exhibit a strong seasonality in their breeding activities is controlled by annual environmental cues related to climate and feed availability. Photoperiod, water temperature, rainfall, food availability, water quality and water level are environmental factors shown to synchronize the reproductive cycle to the optimal time of the season. In temperate regions photoperiod and/or temperature changes are the main cues controlling seasonal reproduction and thus the initiation and completion of puberty.

Pubertal development is particularly well studied in salmonids, such as rainbow trout, Coho salmon, and Atlantic salmon (Taranger *et al.*, 2010). As an example, the early puberty phenomenon in male Atlantic salmon can be observed at very different life stages; in freshwater parr (typically at 10–30 g), in post smolts after one summer in seawater (150–500 g), and after one sea winter (2–5 kg). The Atlantic salmon can also delay puberty into 2 or more years in seawater as fully-grown adults. Hence, male maturation shows considerable plasticity when it comes to age and size at puberty. This seems to be in particular affected by the somatic growth rate, but also by photoperiod and water temperature. These environmental conditions also affect females that usually mature at a larger body size than males, mainly because of the much higher metabolic demands of vitellogenesis/egg production, compared to spermatogenesis. Thus, size seems to matter in females more than in males. On the other hand, size also matters in males. Males that mature after one sea winter are larger than siblings that mature after two or three years in seawater, suggesting that the more rapidly growing individuals within a family will mature earlier than slower growing siblings.

Photoperiod manipulation can inhibit, or significantly delay, puberty in Atlantic salmon by using continuous light during the winter period, when initiated shortly after the winter solstice. An increasing photoperiod after the winter solstice usually triggers the decision to mature. However, only those individuals that meet the energetic and/or body mass threshold when experiencing an increasing day length, will initiate puberty. Those that do not meet these requirements will delay the decision to mature until the following spring (Fig. 1).

The same pattern seems to occur in several other fish species, where there is a strong relationship between somatic growth rates and age at puberty. Hence under farming conditions, high growth rates and/or high adiposity often result in precocious male puberty, compared to wild fish.

By advancing the seasonal perception of spring/summer via an artificially long photoperiod during the winter months, fewer fish are believed to have reached the required size and energy status when the “window” for puberty requires a decision and has been shifted back several months. Studies have also demonstrated that a delay of the normal increase in photoperiod during the winter months enable more fish to attain puberty in the upcoming spawning season. This principle seems to apply both in rainbow trout and Atlantic salmon, the species where most of photoperiod manipulation studies have been conducted. Based on such observations, photoperiod protocols have been developed to delay puberty in Atlantic salmon on-growing farms enabling improved growth performance, and typically delaying puberty for a full year. However, the precise effect of a specific photoperiod treatment will depend on the natural seasonal timing of spawning in a species or population. Photoperiod protocols that are effective in autumn spawning Atlantic salmon, for example, may not be effective in winter and spring spawning rainbow trout. Moreover, the outcome of the photoperiod treatment can also depend on the ambient water temperature cycle, e.g., in areas with higher sea water temperatures (i.e., conditions more favorable for rapid growth), the temperature/growth effect may override the photoperiodic cue for the timing of maturation.

Also depending on time in season and life-stage, a given photoperiod treatment can have opposite effects on age and size at puberty. For example, continuous light and elevated water temperature can induce early male maturation around the time of sea water transfer (Fjelldal *et al.*, 2011) at the post-smolt stage. In this case, high water temperatures and larger fish size increases the likelihood of males entering puberty early when exposed to a long photoperiod signal.

Fig. 1 Increased growth rate normally results in the fish reaching puberty at an earlier age. Such early puberty is often found under the rapid growing conditions normally found in aquaculture. In fish species living in temperate zones spawning is often confined to a short optimal period in the year, and a delay in puberty to later years will allow a prolonged growth period. This can in turn result in both a delay in age at maturity and larger body size at puberty, despite the overall slower growth rate. Figure modified from Taranger, G.L., Carillo, M., Sculz, R.W., *et al.*, 2010. Control of puberty in farmed fish. General and Comparative Endocrinology 165, 483–515.

Early puberty is also a common problem in aquaculture of other finfish species such as the European sea bass, the Atlantic cod, and Atlantic halibut. The problem is most commonly seen in males. As an example, male European sea bass normally reach puberty at two years of age, whereas females normally reach puberty at three years of age. By contrast, in aquaculture, some males reach puberty already at an age of one year. While the largest males are the ones that are likely to mature, their growth rate is hampered compared to immature males during the years to follow (Carrillo *et al.*, 2015). A similar situation is seen in the Atlantic halibut, where puberty in males typically occurs at an age of 4–5 years and at a size of around 2 kg in wild stocks. However, under farming conditions males typically mature at an age of 2–3 years at the same size as wild males. Upon reaching puberty, the male halibut typically show a much slower growth during the subsequent years compared to the still immature females. Hence, it is beneficial to use all-female populations in halibut farming. Also, in Atlantic cod puberty occurs earlier under farming condition than found in natural populations. Atlantic cod of the northeast arctic cod population usually enters puberty at 4 to 8 years, while the Norwegian coastal cod population does so starting at 3 years of age. This difference disappears under farming conditions as all tested stocks reach puberty at 2 years of age at 1.5–2 kg. Some cod mature even earlier at 1 year of age, and a mean body weight below 300 g creating major problem for cod farming sustainability.

Photoperiod treatments can delay puberty in farming of both sea bass and Atlantic cod, but the protocols are often found to be less effective when applied superimposed on the ambient light in sea cages as opposed to indoor tanks with full photoperiod control. Hence, more research is needed to refine photoperiod protocols for different species and strains for sea cage aquaculture.

The Endocrine System Mediates Environmental Signals to Regulate Gonad Maturation

One of the first tangible signs of puberty is an accelerated growth of the gonads in both sexes. Until puberty, gonadal and somatic growth show a similar pace (allometric growth), i.e., the gonado-somatic index (GSI, gonad weight expressed as per cent of the total body weight) is normally small and constant. At puberty, a superallometric growth phase of the gonad starts, the gonads grow faster than other organs/the rest of the body, and therefore the GSI increases.

The specific activation of gonadal growth is triggered by an increased release of gonadotropic hormone from the pituitary gland. The most detailed information on changes in blood hormone levels is available for salmonid species, like Atlantic and Pacific salmon and rainbow trout. In these species, the pituitary release of follicle-stimulating hormone (Fsh) increases when gonad growth starts; luteinizing hormone (Lh), the other gonadotropic hormone, is not secreted until much later close to the spawning season. Therefore, the initiation but also most of the gonadal growth period depends mainly on Fsh in these species.

The structure of the gonads, the cells that responds to the gonadotropic signal from the pituitary differs between the sexes. In the ovary, the follicular layer surrounds the oocytes, consisting of two somatic cell types, granulosa and theca cells. The receptor for Fsh is present in these somatic cells, mainly in the granulosa cells and to a lesser extent in the steroid producing cells of the theca layer (Miwa *et al.*, 1994; Andersson *et al.*, 2009). Upon the increased production and release of Fsh in the pituitary, Fsh stimulates growth of the ovary and the subsequent puberty onset, i.e., the entry into vitellogenesis, the process during which the oocytes accumulate yolk proteins to support embryogenesis after fertilization.

In the males, the receptor for Fsh is expressed by somatic cells in the testis. One of them are the Sertoli cells. These cells are in direct, close contact to developing germ cells during spermatogenesis and Sertoli cells regulate germ cell development via growth factors and cell-cell contacts. For example, Fsh increases Sertoli cell release of growth factors that promote spermatogenesis, such as insulin-like growth factor 3 (Igfb3), but Fsh also reduces the release of growth factors blocking spermatogenesis, such as anti-Müllerian hormone (Amh). Teleost fish are the only vertebrates, in which the interstitial Leydig cells, next to Sertoli cells, express the receptor for Fsh while in common with other vertebrates, these sex steroid producing cells in the interstitial area of the testis express the receptor for Lh (Schulz *et al.*, 2010). As mentioned above, however, this receptor usually is not stimulated by Lh until shortly before the spawning season when plasma Lh levels increase.

Hence, the gonadotropins, in particular Fsh, regulate sex steroid and growth factor production from somatic cells in the testis. The androgens produced by the Leydig cells are able to stimulate full spermatogenesis (Ohta *et al.*, 2007). Again, the respective androgen receptors are expressed by somatic cells, not by germ cells, so that androgens stimulate spermatogenesis indirectly by regulating Sertoli, myoid and Leydig cell gene expression. These somatic cells then modulate germ cell behavior by growth factor or direct somatic-germ cell signaling. In addition to steroid-dependent mechanisms, recent work in rainbow trout (Sambroni *et al.*, 2013) and zebrafish (Crespo *et al.*, 2016) has shown that Fsh changes the expression of hundreds of genes in the testis in a steroid-independent manner. The most prominent examples are again growth factors, such as the already mentioned Igfb3, but also the Leydig cell derived insulin-like peptide 3 (Insl3). In summary, for the initiation as well as completion of pubertal spermatogenesis, at least two parallel signaling systems are operating in the testis: androgens, which can stimulate full spermatogenesis in fish by yet ill defined mechanisms, and – in a sex-steroid independent manner – a set of growth factors that promote mainly the initial, spermatogonial phase of spermatogenesis.

Genetic Background of the Timing of Puberty

Since Atlantic salmon show a large variation for sea age at sexual maturity, it is a good model species to explore the genetic basis of the timing of puberty. It has also been known for a long time that there is a genetic component contributing to time

Fig. 2 Manhattan plot showing the region chromosome 25 under selection for time of maturity in Atlantic salmon. Picture modified from Ayllon, F., Kjærner-Semb, E., Furmanek, T., *et al.*, 2015. The *vgl3* locus controls age at maturity in wild and domesticated Atlantic salmon (*Salmo salar* L.) males. *PLOS Genetics* 11 (11), e1005628.

of maturity in salmonids (Gjerde *et al.*, 1984, 1994). Very recently, new biotechnological approaches served to find specific regions in the salmon genome significantly contributing to the timing of maturation, such as SNP platforms (Johnston *et al.*, 2014; Gutierrez *et al.*, 2015). Also, it has been possible to re-sequence entire genomes of individual wild salmon maturing either early or late and use the information for genome wide association studies (GWAS). This methodology has identified a region in the salmon genome (Fig. 2) explaining up to 36% of the time of maturity phenotype (Ayllon *et al.*, 2015; Barson *et al.*, 2015). The precision of this technology has made it possible to identify a single candidate gene controlling time of maturity in salmon, the *vestigial-like protein 3* (*vgl3*). This protein functions in the hippo pathway as a cofactor for transcription factors. *Vgl3* has previously been identified as an inhibitor of proliferation in gonads of the fruit fly and chicken, and inhibits adipocytes differentiation in mice. Also in humans, the *VGLL3* locus was linked to age at puberty. Changes in fat metabolism may cause changes in age at maturity, since increased adiposity has been linked to maturation in salmon. Further functional studies will show if *Vgl3* and/or associated proteins of the Hippo pathway are regulators of age at maturity and if this applies to fish in general.

Introduction

Although insects are often regarded as negative to our economy because of their phytophagous nature or their ability to act as vectors of diseases, mankind would have difficulties surviving without pollinator species, such as bumblebees and bees. Insects are the most abundant and diverse group of organisms on earth. Having maintained this position for over 400 million years, they have witnessed the rise and fall of the dinosaurs and survived planet-wide extinctions. Despite our best efforts at eradication of numerous pest insect populations, this very speciose group of animals continues to thrive. Insects share a unique combination of attributes that has enabled their unparalleled success. This includes a small body size, the ability to fly, high reproductive potential, the presence of an exoskeleton, their developmental plasticity and ability to undergo metamorphosis. The changes that take place during this process can be extreme, allowing juvenile and adult insects to take advantage of different food sources and adapt in an ever-changing environment.

Insect Life Cycles

Insects do not have an internal skeleton as vertebrates do, instead, they are surrounded by a rigid armor, called the exoskeleton. This exoskeleton or cuticle protects them from desiccation and mechanical injury, but also gives the insect shape and provides a base to which muscles are attached. Although the rigidity of this cuticle protects them, it makes the apparently 'simple' process of growing extremely complex. For the insect to increase in size, the cuticle must be shed periodically and a larger one must be synthesized. During this process of molting a new cuticle is synthesized under the old one, part of the old cuticle is digested and resorbed and finally the remaining old cuticle is shed in a behavioral process called ecdysis.

In this way, the life cycle of an insect is characterized by several successive stages, each separated by a molt. Most insects hatch from eggs into a first juvenile stage. When the immature insect grows, it will pass through a defined number of instar stages (exact number varies depending on the insect species), before completing metamorphosis into the (winged) adult reproductive stage. Three major modalities of metamorphosis can be found within the diversity of insects. These include no changes or ametaboly; partial or incomplete metamorphosis known as hemimetaboly; and complete metamorphosis or holometaboly.

Metamorphosis is a marked change in body form, through which the adult gains distinct features. Ametabolous insects, such as silverfish (order Thysanura), do not undergo metamorphosis. In this design, the immature stages resemble the adult stage, except from the presence of mature gonads and functional genitals. At each molt these insects increase in size and their gonads and genitals develop progressively, until the animal is able to reproduce. Unlike hemimetabolous or holometabolous insects, Ametabola can continue to molt and grow after reaching the reproductively competent stage. Hemimetabolous insects, such as locusts (Orthoptera), cockroaches (Dictyoptera) and true bugs (order Hemiptera), undergo incomplete metamorphosis. The adult morphology of these insects closely resembles that of the instar stages (also called nymphs), but only differs by the presence of functional wings, gonads and genitals. Throughout their life cycle these insects undergo a gradual transformation with a sharp discontinuity at the adult molt, undergoing metamorphosis during a single molt (Fig. 1(A)). Since they maintain a similar body plan throughout their life, juvenile and adult stages of most hemimetabolous insects live in the same habitat and use the same food. Consequently, competition may exist between the needs for growth and the needs for reproduction. Notable exceptions are the mayflies (Ephemeroptera) and dragonflies (Odonata), which evolved quite different nymphal and adult stages, thereby allowing each to exploit a different habitat. Holometabolous insects, such as butterflies (order Lepidoptera), beetles (order Coleoptera), wasps, ants and bees (order Hymenoptera) and flies (order Diptera), undergo complete metamorphosis. In this design, the body plan of the instars (also called larvae) differs drastically from that of adults. These animals are therefore able to populate different niches and separate the needs for growth from those for reproduction. To allow complete metamorphosis, Holometabola go through a non-feeding pupal stage (Fig. 1(B)). Upon hatching, the primordia of the adult organs (such as wings, legs, eyes, genitals, etc.) are already present within the larvae as so-called imaginal discs (Section Holometabola). These imaginal discs will only differentiate to adult organs during metamorphosis in the pupal stage. This innovation resulted in a rapid diversification of insects and the establishment of the holometabolous orders that are living today. According to the 'pronymph hypothesis' (Truman and Riddiford, 1999), the pupal stage in Holometabola corresponds to the nymphal stages in Hemimetabola, while the holometabolous larval stages correspond to the pronymphal stage in Hemimetabola. This pronymphal stage is the period during which hemimetabolous embryos are enveloped by a cuticle, which is shed upon hatching.

Control of Metamorphosis

Independent of the design of the life cycle, postembryonic development is highly timed and choreographed through the action of different factors. Here, we will focus on the action of the lipophilic insect hormones: juvenile hormones and ecdysteroids,

Fig. 1 Hemimetabolous and holometabolous life cycles and hormone titers. (A) Life cycle of the desert locust, *Schistocerca gregaria*, a typical hemimetabolous insect, containing 3 stages: egg, instars (or nymphs) and adult. (B) Life cycle of the tobacco hornworm, *Manduca sexta*, a typical holometabolous insect, containing 4 stages: egg, instars (or larvae), pupa and adult (moth) (Reproduced from Verlinden, H., Vleugels, R., Zels, S., et al., 2014. Chapter three – Receptors for neuronal or endocrine signalling molecules as potential targets for the control of insect pests. In: Cohen, E. (Ed.), Target Receptors in the Control of Insect Pests: Part II, Advances in Insect Physiology. Burlington: Academic Press, pp. 167–303. Available at: <https://doi.org/10.1016/B978-0-12-417010-0.00003-3>). (C–D) Changes in the juvenile hormone (dotted line) and ecdysteroid (full line) titers regulating molting and metamorphosis in (C) the desert locust and (D) the tobacco hornworm (Reproduced from Chapman, R.F., 2012. The Insects: Structure and Function, fifth ed. Cambridge: Cambridge University Press.).

neuropeptides and insulin-like peptides (ILP) during metamorphosis, a process that requires a strictly regulated balance between cell death of the juvenile tissues and proliferation of the adult ones.

Hormonal Control of Metamorphosis

Post-embryonic development of insects is highly dependent upon different types of hormones. The classic insect hormones are the lipophilic ecdysteroids and juvenile hormones (JHs). In several insect model species, such as the fly *Drosophila melanogaster* and the moth *Manduca sexta*, ecdysteroid biosynthesis is initiated through the action of prothoracicotropic hormone (PTTH). PTTH is secreted by a few neurosecretory cells in the brain that terminate in the corpora allata (CA), a pair of highly specialized neuroendocrine organs in the insect's head (see below). Other factors will also influence the ecdysteroidogenic activity of the PG and are discussed by Marchal et al. (2010). The secretion of PTTH is highly timed (Section Growth and Critical Weight) and occurs prior to each molt. PTTH will bind to its receptor Torso, which is present on the membrane of a specialized endocrine organ called the prothoracic gland (PG) (Rewitz et al., 2009). These glands express the so-called *Halloween* genes encoding cytochrome P450 enzymes responsible for ecdysone (E) biosynthesis. The release of E into the hemolymph surges prior to each molt. E will be converted to its active metabolite, the molting hormone 20-hydroxyecdysone (20E), in several non-endocrine tissues. 20E will bind to a nuclear receptor complex of ecdysone receptor (EcR) and ultraspiracle/retinoid-X-receptor (USP/RXR), thereby initiating transcription of different pathways and eventually triggering a strictly regulated cascade of neuropeptides, which induces the typical ecdysis behavioral sequence. For a detailed review on the neuropeptidergic regulation of ecdysis, the reader is referred to Žitňan and Adams (2012). The sesquiterpenoid JH is produced and secreted by the CA. The nature of the molt – larval to larval or larval to adult – is defined by the presence or absence of JH during this critical period. A surge in 20E titer in the presence of JH will ensure juvenile characteristics, resulting in a larval to larval molt. While a peak of 20E in the absence of JH results in a metamorphic molt. Because of this action, JH is also sometimes referred to as the 'status quo' hormone. JH exerts its function through methoprene-tolerant (Met), a basic-helix-loop-helix (bHLH)/Per-Arnt-Sim (PAS) protein. In several insect species, a steroid receptor co-activator (Taiman/SRC) has been identified as a functional partner of Met. JH binding to Met will ensure heterodimerization of Met with Taiman/SRC, allowing the complex to bind E box-like motifs present in the regulatory regions of downstream genes, such as the transcription factor Krüppel-homolog 1 (Nation, 2015).

Titers of these two critical hormones have been studied in a variety of hemimetabolous and holometabolous insect species. The changes in titers during metamorphosis of a representative hemimetabolous and holometabolous insect species will be discussed below.

To successfully fulfil their role in insect development, it is obvious that concentrations of both 20E and JH in the hemolymph must be strictly regulated and important cross talk exists. These concentrations are not only regulated by their biosynthesis, but also by their degradation and secretion. For a detailed review on the factors that regulate the ecdysteroid and JH titers in immature insect stages, the reader is referred to [Niwa and Niwa \(2016\)](#) and [Hiruma and Kaneko \(2013\)](#), respectively.

Hemimetabola

The JH and ecdysteroid titers throughout the final two instar stages of the desert locust, *Schistocerca gregaria*, are shown in [Fig. 1\(C\)](#). During the penultimate instar stage (4th instar) the JH titers are high during the critical period of molting. Consequently, the ecdysteroid peak precedes a nymphal to nymphal molt. On the other hand, in the last instar stage (5th instar) the lack of JH during the critical period results in a nymphal to adult molt. Experimental application of JH during this critical stage in last instars would lead to an extra nymphal stage.

Holometabola

Similar to Hemimetabola, high JH titers during the critical periods of molting result in a larval to larval molt ([Fig. 1\(D\)](#)). The larval-pupal transition in Holometabola is characterized by changes in hormone titers that have no counterpart in postembryonic development of hemimetabolous insects. In the penultimate instar stage (4th instar) of the tobacco hornworm, *M. sexta*, JH titers decline moderately prior to molting. However these titers are still high enough to produce a new larval cuticle and prevent the development of imaginal discs ([Section Holometabola below](#)). In the last larval stage, JH titers drop below detectable levels or reach trace levels right before a small peak in ecdysteroid titer. This first, small ecdysteroid peak in the absence of JH is called the commitment peak and is not sufficient to initiate molting, instead it results in an irreversible commitment to metamorphosis. Consequently, the insect will stop feeding and enters what is called the wandering stage, during which it will seek an appropriate place to pupate. It will also cause the epidermis to switch its genetic program so that it can no longer produce a larval cuticle, but only a pupal cuticle when exposed to the subsequent, 10 times higher, ecdysteroid peak. This second ecdysteroid peak eventually results in the secretion of the pupal cuticle and shedding of the larval one. Moreover, this second peak is accompanied by a peak in JH titer, which regulates the development of the imaginal discs. Due to the absence of the JH receptor in the epidermis at the time of this second ecdysteroid peak, a larval molt is prevented. When environmental conditions are suitable during the pupal stage, the adult molt will be initiated by a peak in ecdysteroid titer. As JH is absent during this surge in ecdysteroids, due to a rise in the level of JH esterase (which metabolizes JH), the adult cuticle can be produced. Application of JH during this ecdysteroid peak, would result in a pupal to pupal molt, indicating that the JH receptor is again present in the epidermis.

Growth and Critical Weight

Metamorphosis is a complex and tightly regulated process that concludes larval growth and results in the transformation to the adult stage. Since growth only occurs in immature stages, adult body size is determined by the size the larva attained when it stopped feeding and initiated metamorphosis. Control of size is therefore tightly connected to the mechanism that controls metamorphosis. Size determination has been well-studied in model insects, such as *M. sexta* and *D. melanogaster*. When the larvae of these holometabolous insects attain their critical weight, growth ceases and the above mentioned endocrine cascade and subsequent metamorphosis is initiated. Critical weight is defined as the weight of the insect at which initiation of metamorphosis can no longer be delayed by starvation, i.e., when last instar larvae have reached a certain body size after a period of feeding and intrinsic growth, the path to metamorphosis is inherently switched on. As long as the larva does not obtain its critical weight, its brain will be unable to release PTTH, the primary inducer of ecdysteroid biosynthesis in the PG ([Section Hormonal Control of Metamorphosis](#)). The attainment of critical weight provides a checkpoint that ensures that larvae have stored enough nutrients to make it through the non-feeding pupal stage, during which these nutritional stores will fuel the development of adult tissues and structures. Larval growth is therefore crucial for effective completion of metamorphosis and the success of reproduction in the adult stage. The mechanism that initiates PTTH and 20E secretion prior to the metamorphic molt, when JH is absent, will control the final body size and can be quite diverse in different insect species.

The attainment of critical weight is controlled by both environmental and genetic factors. The principal genetic regulators of growth are ILP and ecdysone, together with their receptors and signalling pathways. The biosynthesis and secretion of these hormones are in their turn regulated by complex interactions of other endocrine and molecular mechanisms, by environmental factors, such as nutrition, and by physiological mechanisms that sense body size. Also oxygen levels appear to be involved in critical weight sensing. For a detailed review, the reader is referred to [Nijhout \(2015\)](#).

Maturation of the Reproductive System in Immature Stages

The changes that take place during transformation of the juvenile to adult insect depend on the design of their life cycle, hemimetabolous or holometabolous. Nevertheless, molting of the insect to the adult stage inherently entails the development of functional gonads and genitals. Here, we will discuss changes that take place in hemimetabolous and holometabolous insects during metamorphosis with a focus on the reproductive organs. While only gradual changes take place in hemimetabolous insects, holometabolous insects go through a stage with very marked changes. Throughout post-embryonic development growth of internal

organs may result from an increase in cell size and/or cell number. In general, tissues that are destroyed upon metamorphosis undergo cell enlargement, while those that persist undergo cell multiplication.

Hemimetabola

Hemimetabola gradually develop adult features or instar features just resemble those of adults. Two examples of gradually developing traits are the wing buds and the genitalia. At each molt, the wing buds will increase in size, until they form functional wings in the adult stage (**Fig. 1(A)**, wing buds and wings in black). Similarly, the genitalia develop throughout post-embryonic development, but are only functional in the adult stage. Also the gonads are already present after hatching and gradually grow. In many insects, sperm production is already initiated during the last instar, although spermatogenesis continues in the adult stage. Also oogenesis can start in last instars, but vitellogenesis is a typical adult feature. On the other hand, the musculature of instars resembles that of adults, even the flight muscles are already present in instars. Although, these flight muscles still increase in size by an increase in both fiber size and the amount of fibers. Some muscles that are only used during ecdysis disappear in adults. Consequently, also the neuronal supply of these muscles dies. Other changes in the neuronal system are found in the sensory neuronal pathways, where some neurons change their role towards adult behavior.

Holometabola

In holometabolous insects the degree of modifications during metamorphosis depends on the resemblance between the larval and adult stage. Relatively small modifications take place in beetles (Coleoptera), while in flies (Diptera) and butterflies (Lepidoptera) tissues are almost completely rebuilt after hydrolysis and phagocytosis. The pupal stage allows the transition between the larval and adult form. During the pupal molt and subsequent pupal stage, all larval organs, except the central nervous system and reproductive organs, are broken down and major internal reconstruction takes place. In the pupal stage all adult features become recognizable, although they are not fully expanded to their adult form. As eclosion only takes place under the appropriate environmental conditions, metamorphosis may already be completed a few hours, days or weeks before eclosion.

Details on the developmental changes during metamorphosis vary between insect species and organs. In general there is an extensive reconstruction of the musculature and the central nervous system (CNS). For instance, flight muscles will be formed and muscles will be attached to the cuticle during the pupal stage. As the adult insect is characterized by a larger brain, compound eyes and larger antennae, the CNS is also thoroughly remodeled. Furthermore, the digestive system of most holometabolous insects undergoes drastic changes due to the different larval and adult diets. Larval stages often feed on leaves, while the adult stage often has a fluid diet. As some organs are remodeled, others are newly formed. These organs develop from imaginal discs, undifferentiated groups of ectodermal cells that will grow into adult tissues only under appropriate hormonal control during pupation. During the larval stages the cells of these imaginal discs only increase in cell number by mitotic division. Ecdysteroid secretion and falling JH levels in the final instar of *D. melanogaster* will signal the imaginal discs to undergo rapid differentiation into adult structures during the pupal stage. The best known and most studied imaginal discs are those of the wings, legs and genitalia. While the imaginal discs of wings and legs are paired, the genital disc is unpaired and bilaterally symmetrical. The genital disc is located in a medial position at the posterior end of the insect. Genital discs are sexually dimorphic, i.e., their morphology and growth are sex-dependent. Genital discs will give rise to the hindgut, analia and internal and external genitalia, but not to the gonads. These organs (testes and ovaries) are formed during the embryonic stage and will slowly develop throughout the larval stages (**Fig. 2(B)**, green structures). Also the genital discs are formed during the embryonic stage and will increase in cell number and differentiate into a male or female disc throughout the larval stages (**Fig. 2(A)**). However, it is only in the pupal stage that these genital discs will develop into the previously mentioned organs (**Fig. 2(B)**). The embryonic genital disc contains three regions, the male genital primordium (MGP), the female genital primordium (FGP) and the anal primordium (AP). During larval development the sex-determination genes and homeotic genes determine the proliferation of the different regions. In female larvae the MGP is brought into a 'repressed state', called the repressed male genital primordium (RMP). In male larvae the FGP will be repressed and is therefore called the repressed female genital primordium (RFP). For a detailed review on the genetic control of genital disc formation and differentiation, the reader is referred to [Estrada et al. \(2003\)](#). In the prepupa the external genitalia (vulva, vaginal plates of female; penis apparatus, clasper of male) start to develop. The genital ducts (oviducts, uterus, vagina, seminal vesicles, ejaculatory duct and sperm pump) and accessory structures (seminal receptacle, spermathecae, accessory glands and paragonia) on the other hand only start development in the early pupa. After development of these reproductive tissues, the testes will make contact with the seminal vesicles, while the ovaries fuse with the oviducts. The adult eventually emerges with a fully formed reproductive system.

Depending on the insect species the freshly emerged adult will be reproductively competent or it will have to go through a period of maturation before being able to reproduce. The time frame in which spermatogenesis occurs, is species dependent. In most insects spermatogenesis already starts in the larval stages and formation of spermatids, and subsequent spermiogenesis, is often delayed until the last larval or pupal stage. In species that do not feed as adults, the whole process of spermatogenesis (incl. spermiogenesis) is completed before adult eclosion. However, in most insect species spermatogenesis is only completed in the adult stage. Often the production of new sperm continues throughout adult life. For a long time, spermatogenesis in insects was not considered to be under hormonal control. However, it has now become clear that in a wide range of insect species, both Hemimetabola as well as Holometabola, ecdysteroids synthesized in the testes can stimulate spermatogenesis ([Nation, 2015](#)). Similarly to spermatogenesis, oogenesis is very species dependent. In general, oocytes get stuck in the prophase or metaphase of

the first meiotic cycle, and a period of maturation in the adult stage is required before ovulation and resumption of meiosis take place. This maturation includes the incorporation of lipids and yolk into the growing oocyte. The yolk precursor proteins are produced by the fat body in a process called vitellogenesis. In most insects, vitellogenesis is considered an adult feature. However, in some Lepidoptera, which do not feed as adults, vitellogenesis is initiated during the last larval or pupal stage and yolk accumulation is completed prior to adult eclosion. Ovarian growth, vitellogenesis by the fat body and uptake of vitellogenin by the developing oocytes is under hormonal control of both JH and ecdysteroids, as well as additional hormonal factors including ILP and neuropeptides (Nation, 2015).

PREGNANCY AND PARTURITION

Pregnancy and Parturition: Teleost Fishes and Elasmobranchs

Mari Kawaguchi, Sophia University, Tokyo, Japan

Keiichi Sato, Okinawa Churaumi Aquarium, Okinawa, Japan

© 2018 Elsevier Inc. All rights reserved.

Introduction

In this article, we focus on reproductive strategies with special reference to the modes of gestation, embryonic nutrition and their evolution in bony fishes (teleost fishes) and cartilaginous fishes (mainly elasmobranchs). According to [Lodé \(2012\)](#), reproductive strategies in these taxa can be classified into the following five types: (1) ovuliparity, where female fish deposit ova in the environment and these are fertilized externally; (2) oviparity, where fertilization occurs internally and embryo development occurs externally; (3) ovoviviparity, where fertilization and embryo development occur internally, but no nutritional derivatives are supplied through the parental body but through yolk reserves, called 'lecithotrophy' (yolk feeding); (4) histotrophic viviparity, where fertilization and embryogenesis occur internally while obtaining organic nutrients from the mother, called 'matrotrophy' (nourished by the mother); and (5) hemotrophic viviparity, where fertilization and embryogenesis occur internally with nourishment derived from the mother's bloodstream usually through a placental analogue. In teleostean fishes, the dominant strategy is ovuliparity. Some groups of fishes show ovoviviparity, histotrophic viviparity or hemotrophic viviparity (internal gestation). At present, only around 800 among more than 33,000 teleostean species are reported to show internal gestation ([Nelson et al., 2016](#)). They are distributed into 15 families or subfamilies as shown in [Table 1](#), suggesting that internal gestation emerged independently several times during the evolution of teleosts. Furthermore, Syngnathidae show a unique reproductive mode in that males can become pregnant. On the other hand, the dominant reproductive form of approximately 1000 cartilaginous fish species is known as internal gestation, and only some skates and sharks are known to be oviparous ([Table 2](#)). In this article, we will describe the manner(s) of pregnancy in (1) female teleostean fishes, (2) male syngnathid fishes, and (3) elasmobranchs.

Pregnancy in Female Teleostean Fishes

Manner of Gestation – From Fertilization to Parturition

The gestational manner of viviparous fishes differs from that of other vertebrates. Male fish often possess a characteristic structure called a 'gonopodium' or 'andropodium', a tubular structure protruding from the posterior of the anal fin, and transfer spermatozoa to the gonoduct of the female through this structure. The female gonoduct is not a derivative of the Müllerian duct, but is developed from the ovary and the peritoneum ([Wootton and Smith, 2015](#)). Therefore, internal fertilization occurs within the ovarian follicle in

Table 1 List of internally-gestating fishes together with their classification and type of matrotrophy

<i>Fish</i>	<i>Classification</i>	<i>Type of matrotrophy</i>
Coelacanth	Latimeriidae	Histotrophy, placentotrophy
Viviparous brotulas	Bythitidae	
Aphyonids	Aphyonidae	Placentotrophy
False brotulas	Parabrotulidae	
Baikal oilfishes	Comephorinae	Histotrophy
Eelpouts	Zoarcidae	
Eel-blennies	Ophiclininae	Histotrophy, placentotrophy
Kelp blennies	Clininae	Histotrophy
Llabrisomid blennies	Labrisomidae	Histotrophy, placentotrophy
Surfperches	Embiotocidae	
Halfbeaks	Zenarchopteridae	Histotrophy
Goodeids	Goodeinae	Histotrophy, placentotrophy
Four-eyed fish	Anablepinae	Histotrophy, placentotrophy
Livebearers	Poeciliinae	Histotrophy, placentotrophy
Rockfish	Sebastinae	Histotrophy

most of the ovoviparous and viviparous teleosts, and embryo development starts either within the ovarian follicle (intrafollicular) or ovarian lumen (intraluminal) in the ovary (Blackburn, 2015). Intraluminal gestation is found in most teleosts, while intrafollicular gestation is found in restricted species such as fishes of livebearers (Poeciliidae), four-eyed fish (Anablepidae), kelp blennies (Clinidae), and labrisomid blennies (Labrisomidae). In this type of reproduction, development of the embryo takes place within the follicle. Most of these fish species carry the same stages of embryos (one brood), while several species incubate different-staged embryos simultaneously as the result of different timing of fertilization (multi broods): two broods in labrisomid blennies (Labrisomidae), five broods in the blackstripe livebearer (*Poeciliopsis prolifica*), nine broods in *Heterandria formosa*, and up to 12 broods in *Clinus superciliosus*.

The gestation period also differs from species to species. For example, the gestation period of coelacanths is predicted to be 3 years, the longest in known vertebrates, while that of guppies is only 4 weeks. Parturition of the offspring occurs at the last stage of gestation.

The ovaries of internally-gestating fishes are well vascularized for oxygen supply to embryos and removal of metabolic waste. Hatching of the embryos occurs before parturition. In general, euteleostean embryos secrete two kinds of hatching enzymes – high choriolytic enzyme and low choriolytic enzyme – used to digest the egg envelope at the time of hatching. On the other hand, in some internally-gestating fishes such as rockfish and platyfish, hatching enzyme genes have been pseudogenized. Because these eggs are surrounded by thin and fragile envelopes, the embryos seem to be able to hatch without needing hatching enzymes. The role of egg envelopes in ovuliparous fishes is mainly protection from environmental (mechanical and chemical) stresses, while in some internally-gestating species, the envelope is thought to function in immunological defense.

Embryonic Nutrition

The fertilized eggs of internally-gestating fishes contain a large amount of yolk protein. In lecithotrophic species, development of the embryos depends only on yolk protein, especially in growth at an early stage. In some other viviparous fishes, the nutrient supply to embryos during development is performed from a different maternal body in addition to the yolk mass of the embryo (matrotrophy). Lecithotrophy and matrotrophy can be distinguished by changes in the weight of embryos during gestation: thus, the former embryos eventually lose their weight during development, and the latter types maintain or gain weight.

Matrotrophy is mainly categorized into the following two types of nutrition to embryos (Blackburn, 2015; Wootton and Smith, 2015): (1) histotrophy, where embryos absorb nutrients of the surrounding environment through mouth or body surface by eating the egg (oophagy), eating their siblings (embryophagy or adelphophagy), or eating maternal tissues (matrophagy); or (2) placentotrophy, where embryos absorb nutrients through placental analogues associated with the embryonic surface and maternal tissues. In placentotrophy, various types of organs of the maternal body connect to embryos for supplying nutrients, as shown in Table 1 (Wooding and Burton, 2008). Livebearer *Heterandria formosa* absorbs nutrients through the pericardial sac, which covers the entire head or neck strap (Fig. 1(A)). The sac is well vascularized to increase the efficiency of transferring organic materials. In the four-eyed fish *Anableps*, the pericardial sac expands ventrally, and adheres tightly to the maternal epithelium (Fig. 1(B)). The butterfly oodeid, *Ameca splendens*, possesses trophotaeniae (ribbon-like extensions from the hind gut epithelium) (Fig. 1(C)). The trophotaeniae and ovarian epithelium are not fused but are in contact, so that embryos can absorb organic materials from the maternal body. Different from fish species whose placental analogue extend from embryonic body as described above, the ovarian trophonemata of *Jennynsia* extends from the maternal epithelium into the mouth and buccal cavity of embryos (Fig. 1(D)).

Fig. 1 Four types of placentotrophy. Modified from Wooding, P., Burton, G., 2008. Comparative Placentation. Structures, Functions and Evolution. Heidelberg: Springer.

Evolution of Viviparity

The genome sequence now decoded of one of the ovoviviparous teleosts, the platyfish *Xiphophorus maculatus*, provides a unique insight into the evolution of inner gestation (Schartl *et al.*, 2013). It has been considered that evolutionary transitions occur from ovuliparity and oviparity evolved to viviparity (Lodé, 2012). Interestingly, 13 homologs of mammalian genes related to placental development were found in platyfish, and three of them seemed to be under positive selection. These results suggest that the mammalian and teleostean placentas are convergent, not homologous, organs (Schartl *et al.*, 2013).

Male Pregnancy in Syngnathids

Manner of Male Pregnancy

Male seahorses possess an embryo-incubating area on their tail, called the brood pouch (Fig. 2). The female fish deposits eggs into this brood pouch, and fertilization occurs immediately. Within the pouch, the embryos are surrounded by a pseudoplacenta. During pregnancy, the brood pouch functions for gas exchange, waste removal, and osmoregulation: the functions are similar to those of the amniotic uterus. Interestingly, based on recent molecular studies, genes involved in these functions of brood pouch are commonly expressed in female internally-gestating fish and also in viviparous amniotes (Whittington *et al.*, 2015). For example, at the end of pregnancy in eutherian mammals, activation of the mitogen-activated protein kinase (MAPK) signaling pathway is suggested to be involved in parturition. In seahorses, genes associated with the MAPK signaling pathway are also upregulated at the post-parturition stage (Whittington *et al.*, 2015).

Embryonic Nutrition

Although viviparous female fish species supply nutrients to embryos during pregnancy, paternal nutrition transfer (patrotrophy) in seahorses is somewhat equivocal. According to Linton and Soloff (1964), this is not essential because embryos can develop even during *in vitro* incubation. Recent molecular analysis showed that Apolipoprotein M genes involved in lipid transport are expressed in the brood pouch during pregnancy. This evidence suggests that patrotrophy might occur in seahorses by providing histotroph (Whittington *et al.*, 2015).

Formation of Brood Pouch and Evolution

Formation of the brood pouch in the pot-bellied seahorse was reported as follows (Kawaguchi *et al.*, 2017). The pouch formation was initiated from linear projections of epithelia on both ventrolateral sides of the body. The projections elongated toward the

Fig. 2 Interior of the seahorse brood pouch. (A) Before the uptake of eggs and (B) after the uptake of eggs from female. Scale bar=1 mm.

Fig. 3 A plausible pathway of brood-pouch formation in the male seahorse. The primordium of the brood pouch first appears as linear projections at both ventrolateral sides of the body. The projections become fused at the body midline. Differentiation of brood-pouch tissue begins, and the pseudoplacenta first appears on the dorsal side of the pouch. The pseudoplacenta entirely surrounds the pouch. Finally, the pouch folds are formed, ready to incubate embryos. Reproduced from Kawaguchi, M., Okubo, R., Harada, A., *et al.*, 2017. Morphology of brood-pouch formation in the pot-bellied seahorse *Hippocampus abdominalis*. *Zoological Letters* 3, 19.

ventral midline, and eventually fused together. Then, brood-pouch specific tissues such as pseudoplacenta differentiated, and finally, a pouch-fold ready to incubate embryos was developed in the fully formed brood pouch (**Fig. 3**).

Syngnathid fishes including seahorses, all of which possess the brooding area, commonly possess an elongated body with a series of bony rings and no pelvic fin (Nelson *et al.*, 2016). Syngnathids are mainly divided into two groups, Urophori and Gastrophori. The brooding structure of the Urophori is located on the tail, and that of the Gastrophori is on the abdomen. Interestingly, the brooding structure has diverged during evolution as summarized in **Fig. 4** (cited from Wilson *et al.*, 2003). (1) In the simplest case, the structure is such that eggs are attached to the surface of the ventral side of the male body either with only mucous or within membranous compartments of the male body. This type is found in straight-nosed pipefish (genus *Nerophis*), sea dragons (genus *Phyllopteryx*) and fragtail pipefish (genus *Doryrhamphus*). (2) In the intermediate case, the eggs attached onto the male body are further protected by skin elongated from both ventrolateral sides. The skin fold covers the eggs either partially, as found in the genus *Corythoichthys*, or completely, as found in some forms such as the deep-body pipefish (genus *Kaupus*) and pipefishes (genus *Syngnathus*). (3) In the most complicated case a baggy structure is used to incubate the eggs. This type is found in seahorses (genus *Hippocampus*). The brood pouch has an entrance to receive the eggs from female fish and for parturition.

These differences in brooding structures also affect the structures of eggs. The egg envelope of seahorses is thinner than that of the messmate pipefish (covered with pouch folds) or the alligator pipefish (simple form of the brooding structure). One of two kinds of hatching enzyme genes of seahorses has been pseudogenized, while the latter two species possess complete sets of hatching enzyme gene. Similar evolutionary events were observed in ovoviviparous fishes as mentioned above, suggesting the convergent evolution of hatching enzyme genes in pregnant female and male fishes.

Fig. 4 Evolution of syngnathid fishes. Brood pouch types are shown with increasing complexity within the *Urophori* and *Gastrophori*. Modified from Wilson, A.B., Ahnesjö, I., Vincent, A.C., Meyer, A., 2003. The dynamics of male brooding, mating patterns, and sex roles in pipefishes and seahorses (family Syngnathidae). *Evolution* 57, 1374–1386.

Elasmobranchs

Manner of Elasmobranch Reproduction

The strategy of reproduction of elasmobranchs conventionally classified into oviparity and viviparity: viviparity is the major mode of reproduction, while oviparity is found only in the demersal groups, such as bullhead sharks (*Heterodontidae*), carpet sharks (*Orectolobidae*), catsharks (*Scyliorhinidae*), and skates (*Rajidae*). These species lay relatively large eggs encased with hard capsules of a species-specific shape, and the embryos consume nutrition only from the yolk (i.e., are lecithotrophic).

The cycles of reproduction in elasmobranchs are generally long and vary between species. The major cycles in viviparous species are annual, biennial, and 3-year cycles, and the cycle type is determined by the periods of vitellogenesis and gestation. Brood size differs for each species and for the body size of each individual: being generally small in the oophagous or lipid-rich histotrophic species. The species with the smallest brood size are eagle rays (*Mobulidae* and *Myliobatidae*), generally with only one embryo per uterus. The sand tiger shark has the smallest brood size among sharks; usually only one embryo is found in each uterus as a result of embryonic cannibalism. The brood sizes are generally large in placental species like hammerhead sharks (see Fig. 5). The largest brood size ever recorded was a whale shark landed in Taiwan, nurturing 304 embryos. In other groups, the blue sharks (80 embryos), tiger sharks (70 embryos), and probably the sleeper sharks also produce large broods (Castro, 2011).

Fig. 5 A litter of embryos of the smooth hammerhead shark, *Sphyrna zygaena*. Each embryo has a placental connection to the mother's uterus via an umbilical cord.

Embryonic Nutrition

According to Wourms (1977), the internal gestation of elasmobranchs is classified into the following four types by the patterns of nutrient source to the embryos. (1) Lecithotrophy is the simplest and the most ancestral mode of nutrition among internally-gestating elasmobranchs, found in various lineages. The dry intrauterine embryo loses organic weight during gestation. Some spiny dogfishes (Squaliformes) and electric rays (Torpediniformes) are typical examples of this mode. (2) Placentotrophy is the most derived mode of reproduction in elasmobranchs, as it is only recognized in the carcharhiniform sharks. Like other groups, the embryos are initially dependent on nutrition from their own yolk sac. But later, the yolk sac is modified into a placenta to attach to the uterine wall, and the embryos are nourished by the maternal inputs that are shunted to them directly from maternal blood. Hence, this is termed a yolk-sac placenta (Fig. 6). Each intrauterine embryo is encased by a thin, membranous egg case inserted between the uterine wall and placenta. The reproductive cycle of this group is generally biennial with about 1-year gestation periods. (3) Histotrophy is a type of maternal contribution to produce larger neonates than simple lecithotrophy by reducing the number of offspring. It is difficult to distinguish this mode from lecithotrophy without definition of characteristics in the weight gain of the embryos compared with the initial fertilized ova. Musick and Ellis (2005) defined a matrotrophic contribution as a weight loss of less than 20%, or as weight gain during development. There are many categories of histotrophy in sharks and rays. The simplest mode is the mucoid (limited) form of histotrophy that is characterized by producing clear, relatively nutrient-limited fluid secreted from the maternal uterus. The tiger shark is one of the most obvious histotrophic sharks, and its embryos appear to reach gains of 1092% in dry weight during gestation. Lipid histotrophy by producing lipid-rich fluid (uterine milk) from highly developed 'trophonemata' in the uterus is found in the eagle rays (Myliobatiformes), and extreme weight gain occurs during gestation. Based on records of captive-born manta rays (*Mobula alfredi*) in the Okinawa Churaumi Aquarium, the embryo increases its weight to over 50 kg (in wet weight) after 1 year of gestation, and this appears to be the largest weight record of neonates in elasmobranch reproduction. Finally, oophagy (and adelphophagy) is one of the primary modes of embryonic nutrition in lamniform sharks (Wourms, 1977). The intrauterine embryos are initially nourished from their own small yolk sac, and subsequently ingest unfertilized ova ovulated from the maternal ovary into the uterus as their main nutrient source (Fig. 7). Such ova used for nutrition are generally smaller than fertilized ova, and are encased together with several other ova in the shell gland and transferred into the

Fig. 6 The yolk-sac placenta (pl) and umbilical cord (um) of a term embryo taken from a pregnant blacktip shark, *Carcharhinus limbatus*. The thin, yellowish egg case (eg) is entwined with the surface of the placenta. Scale=10 cm.

Fig. 7 A white shark embryo with a large yolk stomach (ys) full of nutrient ova. Scale=10 cm.

uterus. In the sand tiger shark (*Carcharias taurus*), the first embryo in the uterus feeds on its sibling embryos: a phenomenon known as adelphophagy (fraternal cannibalism). Oophagy is also found in carcharhiniformes (Genera *Pseudotriakis* and *Gollum*) and Orectolobiformes (Genus *Nebrius*), but this form is distinguished from lamnoid oophagy by the strategy of supplying nutrient ova and in terms of its evolutionary origins. According to Lodé (2012), oophagy is one types of histotrophy. The recent studies indicate that the nutrition of embryos of these type of sharks appears to be more complex than estimated previously as embryos probably rely on a changing source of nutrition over the course of their development. The embryos depend on at least three major sources of nutrition (Gilmore, 1993): yolk-sac lipids (lecithotrophy) in the initial phase; uterine milk (lipid histotrophy) in the second phase verified by Sato *et al.* (2016); and nutrient eggs in the third phase. Hence, the structure of the uterine epithelium in the histotrophic phase is completely different from that during late gestation after the oophagy phase as it needs to function for oxygen supply.

Viviparity in Reptiles and Amphibians

Daniel G Blackburn, Trinity College, Hartford, CT, United States

© 2018 Elsevier Inc. All rights reserved.

Glossary

Chorioallantois The vascular respiratory membrane that lines the eggshell in reptiles, birds, and mammals. It contributes to placental formation in viviparous reptiles and mammals.

Fetal membranes "Extraembryonic" tissues of reptiles that lie external to the embryo, such as the yolk sac and chorioallantois. They function in protection and gas exchange. In viviparous lizards and snakes, they contribute to placentas.

Lecithotrophy The developmental pattern in which yolk of the ovum provides nutrients for embryonic development. Lecithotrophy occurs in oviparous species and most viviparous species.

Matrotrophy The developmental pattern in which maternal nutrients are provided to the embryo by means other than yolk of the ovum (e.g., placental tissues, oviductal secretions, or sibling yolks).

Oviparity The reproductive mode in which females lay unfertilized or developing eggs that complete their development and hatch in the external environment.

Ovoviviparity An archaic term that was once applied to a variety of egg-laying and live-bearing reproductive modes. Among them are patterns now termed "lecithotrophic viviparity," "oviparous egg-retention," and "pseudoviviparity."

Placenta An organ formed through an intimate association of fetal and maternal tissues that functions in gas exchange and/or nutrient provision.

Pseudoviviparity An unusual form of oviparity in which eggs are fertilized externally and are brooded in some parental structure such as the stomach, vocal sacs, or skin pouches. This pattern occurs in a few frogs and fishes.

Viviparity The reproductive mode in which embryos develop to term inside the female reproductive tract and are born as larvae, altricial neonates, or well-developed offspring.

Yolk sac Extraembryonic tissues that surround and digest the yolk. The yolk sac contributes to placental arrangements in viviparous reptiles, therian mammals and some fishes.

Reproductive Patterns

Parity Modes and Embryonic Nutrition

Viviparity ("live-bearing reproduction") is a pattern in which pregnant females maintain developing embryos inside their reproductive tracts and give birth to their offspring. The alternative to viviparity is oviparity ("egg-laying reproduction"), in which females lay fertilized or unfertilized eggs. Viviparity in reptiles is of particular interest because it has evolved on more than 115 separate occasions, more than in all other vertebrates combined (Blackburn, 2015). Some viviparous reptiles and amphibians have evolved elaborate specializations (such as placentas) by which pregnant females provide nutrients to their developing embryos. Viviparity has been studied extensively to determine how it is accomplished and how and why it has evolved. Although most reptiles and amphibians lay eggs, viviparity occurs in many species of squamates (lizards and snakes) as well as in various caecilians (limbless amphibians) and a few frog and salamander species. Other extant reptiles (crocodilians, turtles, and the tuatara) and the great majority of living amphibians are oviparous. Viviparity also characterizes most mammals and is present in many fishes and invertebrates.

Oviparous embryos obtain nutrients from yolk of the ovum, a nutritional pattern called "lecithotrophy" ("lecithos" being Greek for "yolk"). Lecithotrophy also occurs in most lineages of viviparous vertebrates, including most live-bearing squamates and amphibians. Other viviparous species (like most mammals) have evolved "matrotrophy," in which the pregnant female provides nutrients to her embryos by some alternative means (e.g., uterine secretions, or a placenta [termed "placentotrophy"]). Lecithotrophy and matrotrophy are extremes of a continuum. Thus, in many viviparous species, most nutrients come from the yolk, but these nutrients are supplemented by matrotrophic sources. Likewise, in some viviparous species, nutrients for early development come from the yolk while later in development they are derived from other maternal sources. Viviparous species with a substantial degree of matrotrophy include only a few species of live-bearing lizards and amphibians.

In literature of the 19th century, some zoologists used the term "ovoviviparity" to distinguish the live-bearing patterns of reptiles and fishes from (the so-called) "true" viviparity of mammals. This distinction was based on the mistaken belief that live-bearing reproduction in reptiles is a simple phenomenon in which eggs are merely retained in the female oviduct and hatch during birth. An additional problem is that "ovoviviparity" was used in widely discrepant ways, through confusion between reproductive products (egg vs. neonate) versus embryonic nutritional modes. Accordingly, the word has been abandoned by most researchers in favor of such alternatives as "lecithotrophic viviparity," "oviparous egg retention" and "larviparity" (see below).

Functional and Evolutionary Issues

The widespread phylogenetic distribution of viviparity among animals has important functional and evolutionary implications. For embryos to develop in the maternal reproductive tract typically requires specializations for embryonic gas exchange. Likewise, matrotrophic viviparity requires specializations for nutrient transfer from the pregnant female to her embryos. Viviparity clearly has advantages as well as disadvantages that vary between animal groups. Studies of reptiles and amphibians have contributed markedly toward our understanding of how viviparity is accomplished and how it has evolved.

Viviparity in Reptiles

Phylogenetic Distribution

Among living reptiles, viviparity is confined to lizards and snakes, where it characterizes nearly 20% of the species. At least 13 families of lizards have viviparous species, including such families as skinks, chameleons, phrynosomatids, liolaemids, cordylids, geckoes, xantusiids, anguids, and lacertids (Stewart and Blackburn, 2015). Among snakes, viviparous habits occur in species of 14 families, including boids, colubrids, natricids, viperids, elapids, typhlopids, aniliids, and uropeltids (Blackburn and Stewart, 2011). Viviparous lizards and snakes are distributed worldwide and occupy every habitable continent, in latitudes that range from the equator to the Arctic Circle. They also occur in tropical, subtropical, temperate, and sub-arctic climes, as well as deserts, tropical rainforests, boreal forests, and even oceanic environments. Furthermore, among the viviparous squamates are forms that are terrestrial, arboreal, fossorial, and aquatic, and ones that range in size from small skinks of montane New Zealand to the enormous boas of the Brazilian rainforest. Fossil evidence indicates that viviparity also characterized several extinct reptilian groups, including ichthyosaurs, plesiosaurs, and the gigantic mosasauroid lizards (Blackburn and Sidor, 2014).

Viviparity in squamates is displayed at a variety of taxonomic levels. A few small families are entirely viviparous, such as the families Xantusiidae (night lizards) and Uropeltidae (shield-tailed snakes). However, viviparity usually is manifested at subgeneric levels. Recent reviews have documented 10 genera of snakes and 25 genera of lizards that include both oviparous and viviparous species (Blackburn and Stewart, 2011; Stewart and Blackburn, 2015). A few lizard species contain both oviparous and viviparous populations, such as the European lizard *Zootoca vivipara* and the Australian skink *Saiphos equalis*.

Reproductive Parameters

Gestation length varies widely among viviparous squamate species. In lizards and snakes, pregnancy commonly lasts 2–4 months, and (outside of the tropics) typically is timed to correspond with the warmer months of summer. Longer gestation periods occur among elapid seasnakes, in which pregnancy can last 6–8 months. Gestation lengths of about a year have been documented in a few lizards of cold climates (e.g., *Liolaemus magellanicus* of southern South America) and also occur in *Mabuya* skinks of tropical South America.

Litter sizes of viviparous squamates also vary widely. At one end of the range lie the New Zealand geckoes of the genera *Hoplodactylus* and *Naultinus*, which give birth to ≤ 2 offspring. At the other extreme lies the horned lizard *Phrynosoma douglasii* of North America, in which litter size averages 15 but can range up to 31 offspring. The African chameleon *Trioceros jacksonii* holds the record among viviparous lizards, with litters that range from 10 to 50 neonates. Viviparous snake species show a large range of litter sizes. Very small litters are exhibited by the sea snake *Lapemis curtus* (2–3 offspring) and the rattlesnake *Crotalus atrox* (which averages 4.5 offspring). The largest litters have been documented in various live-bearing vipers and elapid snakes, in which pregnancies have been reported to yield 80 to more than 100 offspring.

How Pregnancy is Accomplished

In viviparous squamates, eggs complete their development within the uterine portion of the maternal oviduct. Although the oviduct of oviparous reptiles secretes the eggshell, in viviparous squamates, only a thin, rudimentary shell membrane is deposited. Accordingly, the shell glands of live-bearing forms are reduced. Parturition (birth of the neonate) in viviparous squamates is functionally equivalent to oviposition of the egg.

Oviparous and viviparous squamates differ in the length of time eggs develop inside the oviduct. In oviparous forms, the time between fertilization and oviposition ranges from a couple to several weeks in duration, during which time the eggshell is deposited. As a result, about 25% of the entire developmental period (i.e., the time between fertilization and hatching) commonly precedes oviposition, and the embryo typically is in the limb-bud stage when the egg is laid (Shine, 1985; Blackburn, 1995). In a few oviparous lizards, the female retains the eggs for a longer proportion of the developmental period, and the embryo is more advanced at oviposition. This pattern of “oviparous egg-retention” may be an intermediate evolutionary stage toward viviparity.

Modest information is available about endocrinological control of pregnancy and parturition. Progesterone produced by the corpus luteum (the post-ovulatory follicle) has been implicated both in retention of eggs in oviparous species and in maintenance of gestation in live-bearing ones. However, viviparous species vary in progesterone profiles during gestation and differ according to whether the CL is essential for maintenance of pregnancy. This variation is evidence that viviparous reproduction has evolved via different mechanisms in unrelated lineages (Blackburn, 2006).

Fetal Maintenance and Placentation

For embryos of oviparous squamates, respiratory gases (oxygen and carbon dioxide) are exchanged with air that surrounds the egg, and water is taken up from the soil (Fig. 1). Nutrients for their embryonic development and growth are derived from the yolk, and calcium is provided via the yolk and the eggshell. In contrast, in viviparous squamates the embryo's physiological needs are met by maternal tissues. Accordingly, the uterine oviduct supplies oxygen and takes away carbon dioxide. It also supplies water and (given absence of an eggshell) provides calcium. Although most viviparous squamates are highly lecithotrophic, uterine tissues commonly supply at least small amounts of organic and inorganic nutrients (Stewart and Blackburn, 2015). Some lizard species are highly matrotrophic, with the oviduct providing nearly all of the nutrients for development (Blackburn, 1993).

In oviparous squamates, physiological exchange with the external environment is accomplished by two fetal membranes – the chorioallantois and yolk sac. As in other oviparous amniotes, the chorioallantois lines the eggshell in the dorsal hemisphere of the egg. With its rich supply of capillaries, it is well-suited for respiratory exchange. The yolk sac lines the ventral eggshell, an ideal location for a membrane involved in water uptake; however, this function has not been demonstrated definitively. Both fetal membranes can be involved in mobilization of eggshell calcium.

In viviparous squamate embryos, the chorioallantois and yolk sac are responsible for physiological exchange with maternal tissues, similar to how they function in oviparous species (Fig. 1). Because the eggshell is vestigial under conditions of viviparity, these two fetal membranes lie closely associated with the oviduct lining. The close association of fetal tissues with the oviduct meets classic criteria for placentation: “intimate apposition of fetal and maternal tissues for physiological exchange.” Thus, the chorioallantois and adjacent uterine lining forms the chorioallantoic placenta. The yolk sac and uterus form the yolk sac placenta.

Microscopic anatomy of the chorioallantoic placenta reveals how it can function so effectively in maternal – fetal gas exchange (Blackburn, 1993). Both the oviduct and the apposed chorioallantois are richly vascularized, and their epithelial coverings are very thin. As a result, the diffusion distance between fetal and maternal blood vessels measures only a few micrometers, enhancing the transfer of oxygen and carbon dioxide. In contrast, the definitive yolk sac placenta is structurally unsuited for gas exchange. Evidence from a few relatively-lecithotrophic species suggests that yolk sac placenta functions in transfer of water and small quantities of nutrients (Blackburn and Stewart, 2011; Stewart and Blackburn, 2015).

A few groups of viviparous skinks are highly matrotrophic. Their placentas are correspondingly specialized. For example, the Mediterranean skink *Chalcides chalcides* exhibits a “placentome,” a specialized region where secretory uterine tissue interdigitates with regions of chorioallantois lined with absorptive cell. In South American *Mabuia*, females ovulate tiny 1 mm eggs, and matrotrophy accounts for most of the nutrients for development. Lizards of this genus also have a placentome, a placenta region where greatly enlarged absorptive cells of the fetal chorion take up nutrients from the uterus (Fig. 2) (Ramírez-Pinilla, 2014). The African lizard *Trachylepis anchietae* is unique among viviparous squamates in that the uterine tissue becomes invaded by fetal cells. As a result the chorion lies in direct contact with the uterine blood vessels, yielding a highly effective means of nutrient transfer (Stewart and Blackburn, 2015). Such a degree of intimacy between fetal and maternal tissues is exceedingly rare among viviparous vertebrates; it is otherwise known only in certain eutherian mammals.

Viviparity in Amphibians

Phylogenetic Distribution and Characteristics

Although most amphibians lay eggs, viviparous habits occur in each of the three major lineages (Wake, 1993; Greven, 2011). Among anurans, viviparity is present in two toad genera of East Africa (*Nectophrynoides* and *Nimbaphrynoides*) as well as the

Fig. 1 Physiological relationship between a squamate egg and its environment under conditions of viviparity (left) and oviparity (right). In the viviparous condition, exchange occurs with the uterine oviduct, and in the oviparous condition, with the air and substrate. In each case, gas exchange occurs via the chorioallantois and water uptake, via the yolk sac. Apposition of the chorioallantois and yolk sac to the oviduct lining in the viviparous condition forms placentas.

Fig. 2 Interface of uterine and chorioallantoic tissues in the placentome of the matrotrophic lizard genus *Mabuya* of South America. The uterine lining forms villi of secretory tissue, whereas the fetal chorion is absorptive. The placentome and areolae are sites of maternal – fetal nutrient transfer.

Indonesian fanged frog *Limnonectes larvaepartus*; it also characterized a now – extinct frog species of *Eleutherodactylus* from Puerto Rico. Among salamanders, viviparity is found in two closely-related European genera, *Salamandra* and *Lyciasalamandra* (Buckley *et al.*, 2007). Among the caecilians, viviparity occurs in species of four families (Dermophiidae, Scolecomorphidae, Typhlonectidae, and Indotyphlidae) (Blackburn, 2015).

Live-bearing amphibians differ according to state of development of the offspring at birth (Wake, 1993). For example, in *L. larvaepartus*, females give birth to young in the tadpole stage, a pattern known as “larviparity.” However, in *Nectophrynoides*, females give birth to metamorphosed young (“pueriparity”). Among viviparous salamandrids, populations vary according to whether the offspring at birth are larval or fully-metamorphosed (Buckley, 2012).

Although gestation lengths in live-bearing amphibians commonly are short, they vary according to habitat and degree of development of the newborn offspring. The 9 month gestation length in *Nimbaphrynoides occidentalis* is the longest known for anurans. However, gestation in the alpine salamander *S. atra* can last as much as 2 or 3 years, a record maximum for viviparous vertebrates.

Embryo Maintenance and Nutrient Provision

In all viviparous amphibians, fertilization is internal and the offspring develop inside the maternal oviducts. In several species, embryos are relatively lecithotrophic. Matrotrophy commonly is associated with pueriparity, since nutrients provided after fertilization facilitate the production of fully metamorphosed larvae.

Among amphibians with matrotrophic viviparity, oviductal embryos typically consume maternally - supplied nutrients (Wake, 1993, 2015). For example, in the east African frog *N. occidentalis*, embryos ingest oviductal secretions. Embryos of viviparous salamandrids feed upon unfertilized yolks, oviductal secretions, or developing siblings. Developing caecilian embryos commonly use specialized teeth to scrape and ingest nutrient-rich lining of the maternal oviduct. Viviparous *Typhlonectes* embryos combine this sort of pattern with ingestion of sibling yolks and embryos.

Oviparous Analogues to Live-Bearing Reproduction

Some oviparous anurans exhibit patterns that may be functionally analogous to live-bearing reproduction. These include species in which the male or female parent carries eggs in its vocal pouches, stomach, or specialized structures in the dorsal integument (Greven, 2011; Wake, 2015). Such patterns are equivalent to forms of parental care of eggs found in monotremes and fishes. These patterns should not be confused with viviparity, which always entails gestation in the female reproductive tract. The term “pseudoviviparity” can be applied to such patterns in recognition of their superficial similarity to true viviparity.

Evolution of Viviparity

Phylogenetic Origins

The widespread distribution of viviparity and matrotrophy among vertebrates clearly reveals that these patterns have evolved many times. A recent analysis recognized 115 evolutionary origins of squamate viviparity, or about 3/4ths of the 155 vertebrate origins of this pattern that can now be discerned (Table 1) (Blackburn, 2015). Viviparity usually is assumed to evolve irreversibly from oviparity. Several recent papers have found evidence for such a reversal to be both scarce and weak, with the possible exception of a few isolated cases.

The squamate origins of viviparity are widely distributed phylogenetically. Multiple origins have occurred in most families with live-bearing representatives, as well as in several genera (Shine, 1985). For example, viviparity has arisen at least 6 times in the family Phrynosomatidae, with 4 origins in the genus *Sceloporus* (fence lizards) and two in *Phrynosoma* (horned lizards). Families in which

^cRecent analysis suggests that at least 120 to 130 squamate origins may be indicated.

^dBony fishes, excluding their tetrapod descendants.

viviparity has evolved even more often include colubrid snakes (≥ 15 origins) and scincid lizards (≥ 31 origins). Live-bearing habits also have arisen on multiple occasions among extinct reptiles. A recent phylogenetic analysis found that viviparity originated independently in 6 reptilian groups of the Mesozoic and Paleozoic, including mesosaurs, ichthyosaurs, choristoderans, mosasaurs, sauropterygians, and a Cretaceous lizard (Blackburn and Sidor, 2014). Evidence for a seventh such origin has recently been published in a basal archosauromorph. Among amphibians, viviparity has evolved at least 1–2 times in salamanders, 3 times in frogs, and 4 times in caecilians, for a total of 8 or 9 origins (Blackburn, 2015).

As for substantial matrotrophy, this fetal nutritional pattern has evolved in squamates only in the family Scincidae, where it has arisen 4–6 times. Among viviparous amphibians, matrotrophy has originated independently in the 4 caecilian families cited above, once among east African frogs, and at least 4 times among European salamandrids, for a total of 9 amphibian origins (Table 1).

Viviparity as a Reproductive Strategy

As compared to oviparous reproduction, viviparity entails both benefits and costs (Shine, 1985; Andrews and Mathies, 2000; Stewart and Blackburn, 2015). Among its benefits are that a pregnant female can protect her eggs from predators and environmental sources of mortality. She also can incubate the eggs at optimal temperatures for development (through behavioral thermoregulation) and can supplement yolk nutrients with matrotrophic sources. Potential costs include limits that viviparity can place on litter size, offspring size, and reproductive frequency, as well as detrimental effects on maternal ability to locomote, feed, and escape from predators. Viviparity commonly is viewed as a "reproductive strategy" that evolves in a particular lineage when its associated benefits exceed such costs.

How and Why has Viviparity Evolved?

Because viviparity entails egg development within the maternal reproductive tract, it can only evolve in clades with internal fertilization (Wake, 1993). This issue may help account for the frequency with which viviparity has arisen in squamates and caecilians, as well as its scarcity among anurans. However, despite the fact that all reptiles and most salamanders also have internal fertilization, oviparity predominates in these groups. Whether viviparity evolves in a particular group depends on a variety of factors, including selective pressures and constraints (Andrews and Mathies, 2000; Blackburn, 2006). Likewise, evolution of viviparity can require certain structural and functional specializations. For example, in squamates, viviparity is associated with reduction of the eggshell and oviductal glands that form it, as well as increases in vascularity of the uterus and fetal membranes.

The fact that oviparous squamates usually retain their developing eggs for $\geq 25\%$ of development and lay them in the limb bud stage may predispose them toward live-bearing reproduction. In a sense, squamates have already evolved part of the way toward viviparity. Squamates contrast with turtles, crocodilians, birds, and most salamanders, which deposit their fertilized eggs in a very early stage of development. Interestingly, the vast majority of squamates either oviposit eggs at the limb bud stage (typical oviparity) or give birth to their young. This dichotomous distribution is consistent with a punctuated equilibrium model for the evolution of viviparity (Blackburn, 1995). According to this model, the intermediate pattern of oviparous egg-retention (with deposition of eggs in an advanced stage of development) is an unstable strategy that is traversed quickly during evolution. The rationale is that retention of developing eggs in the oviducts requires a very thin eggshell for gas exchange to occur, but that such a thin eggshell would be unable to adequately protect the oviposited egg. Another feature of this model is that placentation and an incipient degree of placentotrophy (placental matrotrophy) evolve simultaneously with viviparity, rather than as subsequent steps, due to the close relationship between fetal and maternal tissues that viviparity involves (Fig. 3) (Blackburn, 2006). Substantial

Fig. 3 Scenario for reproductive evolution in squamates. Viviparity has evolved simultaneously with placentation and incipient placentotrophy, rather than in three separate steps. Substantial placentotrophy and complex placentation have evolved in a few lizard clades (see Blackburn, 2006).

matrotrophy can evolve later (as in the skink genera *Mabuya* and *Chalcides*) as maternal nutrient provision becomes obligatory. The above scenario is consistent evidence that oxygen availability limits embryonic development of eggs held in the maternal oviduct (Parker and Andrews, 2006). In a recent modification of this model, maternal calcium provision to eggs was proposed to evolve prior to viviparity, to compensate for reduction of the eggshell during oviparous egg-retention (Stewart, 2013).

Viviparous squamates are disproportionately represented in cold climates of high altitudes and latitudes. This correlation led researchers to conclude that viviparity arose in cold conditions because pregnant lizards and snakes could thermoregulate their embryos at optimal temperatures, accelerating their development (Shine, 1985). In recent years, this “cold climate hypothesis” has been subsumed into a broader “maternal manipulation hypothesis.” According to this hypothesis, pregnant females can manipulate incubation conditions in ways that affect a variety of phenotypic traits to the benefit of the offspring and the mother (Shine, 2014). While this explanation seems to account for many of the origins of squamate viviparity, it may not apply in all cases, and some aspects remain controversial.

Factors affecting the evolution of viviparity in amphibians have received little attention. One plausible explanation is that viviparity has evolved as a means of protecting eggs from predation. Indirect evidence for predation as a selective pressure comes from the variety of mechanisms for egg protection that have arisen among oviparous amphibians, particularly frogs. As for amphibian matrotrophy, one major benefit in salamanders is that it allows females to produce offspring that are fully developed, bypassing the aquatic, pre-metamorphic larval stage (Buckley, 2012).

Viviparity in reptiles and amphibians is a fascinating phenomenon that continues to receive intensive attention from biologists. Such attention is sorely needed, since we lack data for most species on how pregnancy is accomplished and how embryos are maintained in the female oviduct. We also lack information on how and why matrotrophy has evolved. A broad range of approaches is now being applied, including morphological and physiological analyses, experimental approaches, and molecular studies of gene expression during pregnancy (Blackburn, 2006; Van Dyke *et al.*, 2014; Griffith *et al.*, 2016).

Glossary

Adrenal gland The cortex or outer layer secretes steroid hormones, particularly cortisol, in response to ACTH secreted by the anterior pituitary gland.

Anterior pituitary Structure at the base of the hypothalamus that secretes luteinizing hormone (LH), follicle stimulating hormone (FSH), prolactin (PRL), adrenocorticotrophic hormone (ACTH), thyroid stimulating hormone (TSH) and growth hormone (GH) hormones in response to releasing hormones secreted by the hypothalamus, but PRL secretion is regulated by prolactin inhibitory factor which is dopamine.

Cervix A thick cartilaginous structure between the vagina and uterus that serves as a barrier protecting the developing conceptus within the uterus during pregnancy. During the periparturient period the cervix dilates and forms a birth canal through which the fetus and placenta pass to reach the external environment.

Conceptus The embryo/fetus and associated membranes.

Corpus luteum The endocrine gland(s) formed by the granulosa and theca cells of the ovarian follicle after ovulation that secretes progesterone which is necessary for the establishment and maintenance of pregnancy.

Ferguson reflex A neural response from stimulation of the vagina resulting in the release of oxytocin from the hypothalamus/posterior pituitary into maternal blood.

Hypothalamus The structure at the base of the brain that regulates many physiological functions through secretion of hormones.

Labor The process in which the mother's uterine contractions physically force the offspring out of the reproductive tract via the cervix and vagina into the external environment.

Luteolytic hormone Hormone, particularly prostaglandin $F_{2\alpha}$ that causes functional and structural demise of the corpus luteum.

Luteotrophic hormone A hormone such as luteinizing hormone from the anterior pituitary gland or chorionic gonadotropin from placenta that stimulates secretion of progesterone by the corpus luteum.

Parturition The process of giving birth to offspring.

Periparturient The time immediately preceding, during, and immediately following parturition.

Placenta Fetal membranes that include the chorion, allantois and amnion. The chorion and allantois fuse to form the chorioallantois which transfers nutrients, waste products and gases between maternal blood and the fetal blood. In many species, the chorion secretes progesterone.

Posterior pituitary Structure at the base of the hypothalamus that secretes oxytocin and vasopressin in response to neurological signals.

Progesterone block During pregnancy, progesterone from the corpus luteum and/or placenta sustains the pregnancy by inhibiting uterine contractions and other activities that would lead to premature delivery of the fetus and placenta.

Prostaglandin $F_{2\alpha}$ The luteolytic hormone that causes functional and structural demise of the corpus luteum.

Uterus The major component of the female reproductive tract in which the conceptus (embryo/fetus and placenta) develop. It has an outer muscular layer known as the myometrium and an inner secretory layer known as the endometrium.

Introduction

Pregnancy is established and maintained in subprimate mammals in response to a series of interactions between the conceptus (embryo/fetus and associated membranes), uterus and/or ovarian corpus luteum (CL) (Bazer and First, 1983; Bazer and Spencer, 2009; Bazer *et al.*, 2008; Bazer, 2015). These interactions prevent functional and structural regression of the CL, or luteolysis. During the peri-implantation period of pregnancy, pregnancy recognition signals from the conceptus to the maternal system are either antiluteolytic or luteotrophic. The functional life span of the CL is controlled by release of prostaglandin $F_{2\alpha}$ (PGF) from either the uterus (subprimate mammals) and/or ovaries (primates, including humans). Pregnancy recognition signals from the trophoblast act in a paracrine or endocrine manner to interrupt either uterine or intra-ovarian production of luteolytic PGF (antiluteolytic) or the hormone may act directly on the CL (luteotrophic).

Mammals have a placenta that surrounds the embryo/fetus and it is through these placental membranes that nutrients and other molecules from the maternal vascular system are transported to the vascular system of the conceptus to support its

growth and development. At some point in fetal development, depending on the species, there is maturation of the hypothalamic-pituitary-adrenal axis that is sufficient to induce parturition which involves expulsion of the fetus and its placenta from the uterus. Each species has a paradigm for producing live offspring so that the species is able to adapt to the external environment with maximum chances for survival of the neonate. This process of giving birth to offspring is called parturition (Latin, *parturio*, to be in labor). There are variations regarding factors controlling parturition; however, there is a common theme across species based on the roles of the fetal hypothalamic-pituitary-adrenal axis in inducing parturition. Parturition in sheep is the “classical” model because it has provided the preponderance of information that has advanced understanding of the endocrinology and physiology of parturition in subprimate mammals.

Pregnancy Maintenance in Ruminants

In ruminants, such as sheep and cows, an ovulatory surge of LH coincident with onset of estrus (Day 0) initiates events that culminate in ovulation about 30 h later. The antiluteolytic signal for pregnancy recognition in ruminants is interferon tau (IFNT) produced by mononuclear cells of conceptus trophoblast. IFNT exerts a paracrine, antiluteolytic effect on the endometrium to inhibit uterine secretion of luteolytic pulses of PGF. Other conceptus and/or uterine products secreted during early pregnancy, for example, prostaglandin E₂ (PGE) and platelet activating factor (PAF) may exert secondary luteal protective effects. The mechanism for pregnancy recognition is similar for sheep, cattle and goats.

Luteolysis is initiated as progesterone down-regulates expression of receptors for progesterone (PGR) in uterine epithelia 12–13 days after onset of estrus. With down-regulation of PGR there is an increase in expression of estrogen receptor alpha (ESR1) and then oxytocin receptors (OXTR) by the uterine epithelia. Oxytocin secreted by the corpus luteum (CL) and posterior pituitary binds OXTR and stimulates pulsatile secretion of PGF by uterine epithelia. IFNT inhibits expression of ESR1 and OXTR mRNAs in endometrial epithelia to abrogate oxytocin-induced release of luteolytic pulses of PGF that ensures maintenance of the CL and its production of progesterone, the hormone of pregnancy. Nevertheless, inter-estrous intervals of 30–35 days result when sheep conceptuses are removed from uteri of ewes on Day 16 or after intrauterine infusions of either highly purified native ovine IFNT or recombinant IFNT (roIFNT) between Days 11 and 15 after onset of estrus. Thus, a secondary endometrial luteolytic mechanism activated between 25 and 30 days post-estrus must be abrogated by the conceptus to allow maintenance of pregnancy. The secondary mechanism for maintenance of CL function has not been established, but neither placental lactogen (CSH1) nor placental growth hormone (GH1) were found to be the secondary “signal” from the conceptus that reinforces the antiluteolytic effects of IFNT.

Binucleated trophoblast cells in sheep conceptuses appear by Day 16 and secrete placental lactogen (CSH1). Placentae of other ruminant species secrete hormones structurally related to pituitary growth hormone (GH) and prolactin (PRL) and they are members of the CSH1 family. Both ovine GH and CSH1 have similar somatogenic activities; however, their circulating levels are regulated differently during the pregnancy. CSH1 is detected in blood of ewes by Day 50 of pregnancy and concentrations peak between 120 and 130 days of the 147 day period of gestation. Concentrations of CSH1 in fetal blood are less than in maternal blood and peak at mid-gestation after which time they may remain unchanged or decrease gradually to term. Concentrations of oGH are low in maternal serum throughout pregnancy and are not correlated with gestational age. Concentrations of oGH are greater in fetal than in maternal serum and greatest during mid-gestation. CSH1 may be critical to maintenance of pregnancy in sheep since lactogenic hormones influence steroidogenesis in CL and transport of water and other nutrients by placental membranes. Lactogenic hormones also stimulate proliferation of cells, expression of PGR, protein synthesis, exocrine secretion of PGF (pigs) by uterine epithelia, mammary growth and lactation. Ovine placental GH1 may have multiple roles in pregnancy.

Pregnancy Maintenance in Rodents

Gestation in rodents lasts 20–22 days, and functional CL must be maintained until Day 17. The transition in rodents, (i.e., rats, mice and hamsters) from recurring estrous cycles to pregnancy is dependent on maintenance of progesterone production by the CL, the main source of progesterone throughout pregnancy (Ben-Jonathan *et al.*, 2008; Soares *et al.*, 2007). Progesterone replacement alone is sufficient to maintain pregnancy in ovariectomized rats. In addition to lacking a true luteal phase during the estrous cycle, rodents do not exhibit a change in source of progesterone from the CL to the placenta. Thus, maternal recognition of pregnancy in rodents involves activation of nonfunctional CL of the cycle into functional CL of pregnancy.

Mating of rodents during estrus results in pseudopregnancy or pregnancy, and the activated CL secrete progesterone for 12–14 days. Extension of CL lifespan past Day 12 after onset of estrus depends on the presence of viable conceptuses within the uterus. A successful pregnancy in rats requires active secretion of progesterone from CL until at least Days 17–18. Therefore, establishment and maintenance of pregnancy in rodents requires two separate endocrine events. The first endocrine event initiated by mating results in diurnal and nocturnal surges of prolactin during the first 12 days of pregnancy or pseudopregnancy in rats. The prolactin is necessary for formation and maintenance of active CL and their secretion of progesterone. Therefore, the luteotrophic effects of PRL during early pregnancy are required to convert a nonfunctional CL of the estrous cycle into a functional CL of pregnancy or pseudopregnancy.

The second endocrine event required for the maintenance of pregnancy in rodents is dependent on implantation and development of normal conceptuses. In pregnant rodents, the placenta and stromal cells that differentiate to form the uterine decidua produce PRL-like hormones that have luteotrophic effects on the CL to ensure production of progesterone during the middle and late stages of pregnancy. The antimesometrial uterine decidual cells secrete numerous hormones, including PRL-like protein B (PLP-B) and decidual PRL-like protein (dPRP). The main luteotropic hormone of the decidua is a PRL-like protein, although uterine decidual cells also secrete PLP-B. Placental lactogens (CSHs) are found in a variety of subprimate mammals, including rodents. However, the only established physiological roles for CSHs are in rodents. In rats, seven members of the PRL gene family are expressed by trophoblast cells of the placenta: placental lactogen-I (CSH-I), CSH1-I variant (CSH1-Iv), CSH1-I mosaic (CSH1-Im), CSH1-II, PRL-like protein A (PLP-A), PLP-B and PLP-C. CSH1-I and CSH1-II have biological activities similar to those of pituitary PRL, including CL maintenance and growth of the mammary glands.

Factors regulating production of CSHs by trophoblast cells are not well known. The ontogeny of CSH1-I expression appears to be linked to differentiation of trophoblast cells during the peri-implantation period. In mice, expression of the CSH1-I gene appears to be regulated by the number of conceptuses and by the pituitary gland. Similarly, factors affecting expression of the CSH1-II gene include the number of conceptuses, genotype of the conceptuses, pituitary via growth hormone (GH), ovarian steroids and nutritional status of the mother. The shift from CSH1-I to CSH1-II is associated temporally with degeneration of the choriovitelline placenta between Days 13 and 14 of gestation.

In rats, PRL is essential for maintenance of progesterone secretion by CL throughout pseudopregnancy. However, in the pregnant rat, removal of the anterior pituitary after mid-gestation does not affect luteal function and pregnancy is maintained. Thus, pituitary PRL is not necessary after Day 6 of gestation in rodents. Given their PRL-like activity and their ontogeny during pregnancy, CSHs are likely luteotrophic factors from the placenta during mid- to late-pregnancy in rodents.

Pregnancy Maintenance in Swine

Estrogens produced by conceptuses between Days 11 and 12 of gestation provide the initial signal for maternal recognition of pregnancy in swine (Bazer, 2015). This signal results in a switch in the direction of secretion of PGF by uterine epithelia from an endocrine direction (i.e., into maternal blood) to an exocrine direction (i.e., into the uterine lumen). A second period of estrogen production occurs between Days 15 and 25–30 of pregnancy in pigs. Injection of exogenous estrogen (estradiol valerate, 5 mg/day) on Days 11 through 15 of the estrous cycle results in CL maintenance for a period equivalent to or slightly longer than pregnancy. This condition of estrogen-induced CL maintenance in non-pregnant pigs is known as pseudopregnancy and it persists for about 120 days. Thus, two phases of exogenous estradiol, similar to that produced by conceptuses on Days 11–13 and Days 15–25–30, are necessary for prolonged secretion of PGF into the uterine lumen. Estradiol may induce receptors for maternal hormones, for example, prolactin, or conceptus secretory proteins, which influence exocrine (into the uterine lumen) secretion of PGF. The first estrogen signal may induce receptors for PRL and the second estrogen signal may be required to replenish those receptors. Administration of estradiol on Day 9 advances the uterine secretory response in pregnant gilts, but leads to conceptus death by Day 16 due to degeneration of the extracellular matrix on the uterine luminal epithelium. An explanation for this “induced” conceptus death is not available, but it may result from asynchrony between the developing conceptus and uterine environment that adversely affects maintenance of the extracellular matrix.

Estrogen induces endometrial receptors for prolactin (PRLR) in pigs, and PRL acts on the endometrium to induce calcium cycling across the epithelium. In pigs, PRL interacts with estrogen and progesterone to increase total recoverable uteroferrin, glucose and PGF in uterine flushings. Available results strongly indicate that prolactin enhances uterine responsiveness to progesterone during periods critical for maintenance of pregnancy.

Pregnancy Maintenance in Horses

The uterine luteolytic hormone in mares is PGF and the conceptus produces an unidentified factor that inhibits uterine secretion of luteolytic pulses of PGF (see Bazer, 2015). In cycling mares, concentrations of PGF in uterine venous plasma and uterine flushings increase between Days 14 and 16 when luteolysis occurs and concentrations of progesterone decline in blood. The amount of PGF bound by luteal receptors is maximal on Day 14 of the estrous cycle and Day 18 of pregnancy. Since CL of mares can respond to circulating PGF during pregnancy, the conceptus must evoke an antiluteolytic mechanism. Pregnant mares have little PGF in uterine fluids, low concentrations of PGF in uterine venous plasma, and no pattern of pulsatile release of PGF (measured as the metabolite of PGF, PGFM) in peripheral plasma. In the presence of the conceptus, endometrial production of PGF in response to cervical stimulation and exogenous oxytocin is markedly reduced, indicating the absence or significant reduction in endometrial receptors for oxytocin in mares during early pregnancy.

The pregnancy recognition signal in mares is not known, but estradiol and/or proteins from the conceptus are likely candidates. There is also some evidence that PGE may play a role in pregnancy recognition signaling in mares. The equine conceptus migrates between the two uterine horns 12–14 times per day between Days 12–18 of pregnancy presumably to inhibit endometrial production of luteolytic PGF and protect the CL for production of P4. The equine conceptus also produces increasing amounts of estradiol

between Days 8 and 20 of gestation. A similar trend, but of greater magnitude, was found for estrone. Attempts to prolong CL lifespan in mares by injection of estrogens have been inconsistent.

Horse conceptuses secrete three major proteins between Days 12 and 14 of pregnancy with molecular weights of greater than 400,000, 50,000, and 65,000. However, the role(s) of those proteins is not known. Estrogens and/or conceptus secretory proteins may provide the maternal recognition of pregnancy signal in the mare by directly or indirectly inhibiting uterine production of luteolytic pulses of PGF.

Pregnancy Maintenance in Rabbits

Rabbits are induced ovulators and multiple ova are ovulated from each ovary approximately 10 h after mating. The oocytes remain fertilizable for about 6 h (Marcinkiewicz and Bahr, 1993). The fertilized ova arrive in the uterus 3 days post-ovulation and implantation occurs on Day 7 at the blastocyst stage of conceptus development. The rabbit placenta is not a significant source of progesterone and the CL are required for pregnancy to go to term. Following a sterile mating, CL form and persist for 14–16 days without support from conceptus products. For both pseudopregnant and pregnant does, progesterone begins to increase 2 days after mating to maximal levels of 12–20 ng/mL between Days 6–8 post-coitum. Between Days 8 and 10 post-mating progesterone profiles of pregnant and pseudopregnant does begin to diverge with concentrations of progesterone in blood declining rapidly after Day 12 to basal levels between Days 16 and 18 of pseudopregnancy. For pregnant does, concentrations of progesterone in blood do not begin to decline until 3–4 days prior to parturition (kindling).

Maternal recognition of pregnancy occurs after implantation between Days 10 and 12 of gestation. Estrogen and a placental luteotrophin interact to maintain progesterone production by the corpora lutea until term (28–35 days). Estrogen from developing follicles is required to stimulate progesterone production by CL for the first 10–12 days of pregnancy, but not to term. Luteal cells of corpora lutea of rabbits express LH receptors; however, LH does not stimulate progesterone production *in vivo*.

Production of a placental luteotrophin is necessary for production of progesterone by corpora lutea to term, but exogenous estrogen does not support progesterone production by corpora lutea of hysterectomized does during late pregnancy. Placentae of rabbits secrete a molecule having immunoreactive GnRH-like activity, but there is no evidence for it being transported from the uterus to the corpora lutea. A putative placental luteotrophic factor with a molecular weight greater than 6–8 kDa does enhance progesterone production by cultured luteal cells. Placental giant cells in rabbits also contain immunoreactive chorionic gonadotropin, and cytotrophoblast cells contain immunoreactive CSH1/PRL. However, the function(s) of those proteins has not been determined.

Pregnancy Maintenance in Cats

The cat, also an induced ovulator, ovulates 25–50 h post-mating (about 24–36 h after the LH peak) with frequent matings reducing the time to ovulation (Verstegen *et al.*, 1993; Brown, 2006). Fertilization takes place in the oviduct up to 48 h after ovulation. Feline embryos enter the uterus at the blastocyst stage, 4–6 days post-ovulation, blastocysts hatch from the zona pellucida on Day 11 and begin implanting by Days 12–13 of pregnancy. Following mating, concentrations of progesterone in plasma increase from about Day 3 to maximal levels (15–90 ng/mL) between Days 10 and 40 of pregnancy, or Days 13 and 30 of pseudopregnancy. Pseudopregnancy typically lasts 40 days and gestation ranges between 56 and 71 days, averaging 63–65 days. By Day 30, circulating levels of progesterone are significantly higher in pregnant than in pseudopregnant queens. The corpora lutea of queens are resistant to luteolytic effects of PGF until after Day 40 of pregnancy.

The placenta does not appear to be a significant source of progesterone during gestation in cats. Concentrations of prolactin in maternal blood increase after Day 40 of gestation in queens and it is considered the *be* luteotrophic. Inhibition of secretion of PRL in the last trimester of gestation causes abortion. Concentrations of PRL are greatest just prior to parturition (5–10 ng/mL) and remain elevated during lactation in response to suckling. Relaxin is produced by the fetal-placental unit, corpora lutea and uterus during pregnancy. Relaxin likely works in concert with progesterone to keep the uterus quiescent and to facilitate parturition by softening the connective tissues of the pelvis and cervix (Sherwood, 2004). Following parturition, queens experience a period of lactational anestrus and resume cycling 2–3 weeks after weaning kittens.

Pregnancy Maintenance in Dogs

Dogs are spontaneous ovulators and fertilization of oocytes occurs 2–5 days after ovulation in the bitch and embryos enter the uterus at the blastocyst stage around Day 10 (Concannon, 1993; Verstegen-Onclin and Verstegen, 2008). Embryos remain free-floating in the uterus until hatching and implantation around Day 16. The ovary is the primary source of progesterone and ovariectomy or hypophysectomy at any stage of pregnancy results in abortion. Since the lifespan of corpora lutea of pregnancy (64–66 days) and pseudopregnancy (60–63 days) are similar, there is no known requirement for signaling between the conceptus and maternal system for CL maintenance, pregnancy recognition or maintenance of pregnancy.

The corpora lutea of bitches are resistant to luteolytic effects of PGF until after Day 40 of pregnancy or pseudopregnancy. The secretion of prolactin increases after Days 30–40 of gestation and it is considered to be luteotrophic. Inhibition of secretion of PRL after about Day 30 of gestation causes abortion. The ovaries and pregnant uterus produce relaxin for uterine quiescence during pregnancy, as well as relaxation of the cervix and pelvic ligaments. Interestingly, it remains detectable in blood of bitches for up to 60 days after parturition.

Endocrine Cascade Leading to Parturition

Subprimate mammals have placentae that include the amnion and amniotic fluid therein that provides support for the embryo/fetus to exist somewhat like a marine mammal and develop symmetrically in a liquid environment. The other two membranes, chorion and allantois, fuse to form the chorioallantois that transports nutrients from the blood of the mother to the blood of the conceptus and allows for the exchange of gases (O_2 and CO_2) between blood of mother and conceptus. At some point in development of the conceptus, varying with species, the fetus and its placental membranes are expelled from the uterus into the external world. Each species has a unique paradigm for producing live offspring that includes development of the fetus in utero, the birth process, and adaptation of the newborn to the external environment so that survival of the offspring is maximized for propagation of the species. The physiological events leading to birth of subprimate mammals is known as parturition (Latin, *parturio*, to be in labor), is the focus of this section of this chapter (see Thorburn and Challis, 1979; Liggins, 1988; Currie *et al.*, 1988; Wood and Cudd, 1997; Challis *et al.*, 2005).

One of the oldest records depicting birth is a stone relief in the tomb of Ti (2450–2320 BCE) showing assistance being given to a cow by applying traction to the limbs of a partially protruding calf and another showing removal of fetal membranes. Around 2000 years later the Greek philosopher Hippocrates proposed that the baby determines the timing of birth. In the 1930s, Joseph Barcroft found that restriction of oxygen and other nutrients to the fetus due to the mother's inability to meet the increasing demands of a developing fetus for nutrients lead to birth (see Liggins, 1988). However, Liggins (1988) published seminal findings establishing that maturation of the fetal hypothalamic-pituitary-adrenal gland axis provides for endocrine regulation of parturition. From the first record over 4400 years ago through to today, the paradigm of pregnancy leading to parturition is that the fetus and placenta signal their presence to the mother, secrete hormones that establish and maintain the pregnancy, prepare the mother's mammary glands for lactation and determine the time of birth.

There are a multitude of variations on the theme of regulatory factors controlling reproduction in mammals and they are likely continuing to undergo evolutionary changes. Each species is exploring to find the “best fit” for maximizing survival of the species. The process of parturition also involves a multitude of variations in factors controlling parturition. However, there is a common theme across species in regulating the major events of reproduction including parturition. Most is known about the physiology and endocrinology of parturition in the ewe, which is the “classical” model that has provided the preponderance of information toward our understanding of parturition in subprimate mammals.

Parturition, once initiated, leads to rapid expulsion of the young from the reproductive tract of the mother to the external environment. The mother prepares for this throughout pregnancy with a gradual change in her endocrine environment to accommodate changes that range from alterations in cardiac function and respiratory functions to mammogenesis and lactogenesis. The placental membranes and the hypothalamic-pituitary-adrenal axis of the fetus mature with advancing gestation and once that maturation process reaches a critical point events leading to parturition are initiated. The key events leading to parturition were established based largely on results from research by Liggins and co-workers with sheep (see Fig. 1).

In fetal lambs the hypothalamus at the base of the brain begins to secrete corticotropin releasing hormone (CRH) into the local portal circulation around Day 100 of gestation. The CRH enters the hypothalamic portal system supplying the anterior pituitary gland. On about Day 125 of pregnancy, the fetal anterior pituitary gland begins to respond to CRH by producing and secreting adrenocorticotropin hormone (ACTH) into the systemic circulation where it can stimulate the adrenal cortex to release cortisol. Arginine vasopressin (AVP) secreted by the hypothalamus may also play a role in parturition by stimulating the secretion of ACTH from the anterior pituitary gland. Beginning around Day 135 of gestation the adrenal cortex of the fetus has matured sufficiently to begin responding to ACTH and secreting cortisol in increasing amounts so that concentrations in fetal blood are maximum 24–48 h prior to the onset of parturition in ewes on Day 147 of gestation. In sheep and in many other species including goats, cows, and pigs, the endocrine events in the fetus leading to production of cortisol and culminating in parturition and birth of the offspring are very similar.

The critical role of the fetal hypothalamic-pituitary-adrenal axis was revealed in an elegant series of studies by Liggins and co-workers. They removed the fetal anterior pituitary gland at the end of the second trimester of pregnancy and found that parturition was delayed significantly. But, when ACTH was administered to the fetus at the end of the second trimester of pregnancy parturition was induced. Likewise removal of the fetal adrenal gland and cortisol prevented parturition while administration of cortisol to the fetus induced parturition. In sheep and cows with deformities in the fetal brain resulting in the absence of hypothalamic secretion of CRH, parturition does not occur normally and fetuses must be removed by Caesarean section. This is because the fetus will continue to grow to an extremely large size and eventually compress the gastrointestinal system of the ewe or cow leading to her death. A similar result was reported for fetal calves with an abnormality of the adrenal gland that prevented secretion of cortisol.

During the last 3–5 days prior to parturition there are significant changes in the endocrinology of the pregnant female (see Table 1). First, concentrations of progesterone in maternal blood decrease rapidly. This is because the placenta stops producing

Parturition – Sheep Model

- Fetus
 - Hypothalamus
 - CRH
 - Anterior Pituitary
 - ACTH
 - Prolactin
 - Adrenal Gland
 - Secretion of Cortisol
 - Placenta
 - Progesterone decreasing, estrogen increasing due to activation of C-21 Steroid 17 alpha hydroxylase enzyme by cortisol
- Maternal
 - Corpus Luteum
 - Progesterone and Relaxin (some species)
 - Regresses due to PGF2-alpha from uterus in response to estrogen and oxytocin
 - Anterior Pituitary
 - Prolactin and Growth Hormone
 - Posterior Pituitary
 - Oxytocin released to stimulate secretion of PGF2-alpha and myometrial contractions
 - Uterus
 - PGF2-alpha secretion increasing
 - Gap junctions increase among myometrial cells and uterine contractions increase

Fig. 1 Parturition: The sheep model. The periparturient endocrine events that occur in the mature fetus initiate the endocrine cascade that leads to parturition. The fetal hypothalamus secretes corticotropin releasing hormone (CRH) that acts on the fetal anterior pituitary gland to induce production and secretion of adrenocorticotropin hormone (ACTH) into the general circulation of the fetus. The fetal adrenal gland responds to ACTH with secretion of cortisol primarily. Cortisol acts on cells of the placenta to activate C21-steroid 17 α -hydroxylase which allows progesterone to be metabolized to estrogens which are key to the initiation of parturition. The shift from progesterone dominance for maintaining pregnancy to estrogen dominance is integral to the cascade that leads to parturition. For example, estrogen activates enzymes that lead to synthesis of prostaglandin F_{2 α} (PGF2-alpha) that plays a major role in parturition, and estrogen increases in expression of receptors for oxytocin on uterine epithelial cells and smooth muscle cells of the uterine myometrium. The mother's hypothalamus secretes oxytocin which acts via its receptors on uterine epithelial cells induce pulsatile secretion of PGF2-alpha and both oxytocin and PGF2-alpha act on the myometrium to induce contractions of the myometrium. In addition to PGF2-alpha causing regression of the corpus luteum to further decrease circulating concentrations of progesterone, it also release relaxin (e.g., pigs) from the corpus luteum which is responsible for dilation of the cervix and relaxation of pelvic ligaments. In other species the placenta is the source of the relaxin (Sherwood, 2004). The decrease in concentrations of progesterone and increasing concentrations of estrogen also induce formation of gap junctions among smooth muscle cells of the uterine myometrium which is necessary for the coordination of contractions among smooth muscle cells to expel the fetus and placenta to complete the process of parturition.

progesterone and starts secreting estradiol and there is regression of the corpus luteum to eliminate that source of progesterone. The sheep placenta produces progesterone; however, cortisol activates the enzyme C21-steroid 17-alpha hydroxylase which converts progesterone to 17-alpha hydroxyprogesterone that can be metabolized further to androgens and estrogens. The fetal gonads in mares provide androgens for synthesis of estrogens by the placenta. The estradiol produced by the placenta increases phospholipase A2 activity and expression of oxytocin receptors in uterine epithelia and uterine myometrium. Phospholipase A liberates arachidonic acid from phospholipids in uterine epithelia for conversion by prostaglandin synthase 2 and prostaglandin F synthase to PGF. Oxytocin from the posterior pituitary gland is released in pulses as the fetal head pushes on the cervix during parturition

Table 1 Characteristics of periparturient endocrine events

Species	Days of gestation	Source of progesterone	Placental C21 Steroid 17 α - hydroxylase	Fetal adrenal hormone	Source of relaxin
Sheep	144–152	CL and Placenta	Yes	Cortisol	?
Goat	146–154	CL	Yes	Cortisol	?
Cow	270–300	CL and Placenta	Yes	Cortisol	CL
Pig	112–115	CL	Yes	Cortisol	CL
Horse	315–360	Placenta	No	Cortisol	Placenta
Dog	64–66	CL	Unknown	Unknown	CL and Placenta
Cat	64–66	Placenta	Unknown	Unknown	CL, Placenta and Uterus
Rat		CL	No	–	CL
Rabbit		CL	No	–	Placenta and Uterus
Primate		Placenta	No	Cortisol DHEA SO ₄	CL+Uterus

Abbreviations: CL, corpus luteum; DHEA-SO₄, dehydroepiandrosterone sulfate.

Fig. 2 The myometrium is composed of smooth muscle cells that are critical to providing the forces of contractions necessary for delivery of the fetus and placenta. A prerequisite for development of strong myometrial contractions is the increase in production of estrogens by the placenta and the decreased progesterone which leads to the formation of gap junctions among myometrial cells that allows them to contract in unison and with increasing force as oxytocin and prostaglandin $F_{2\alpha}$ act via their respective receptors to stimulate uterine contractions. Distension of the uterus and pressure of the fetus on the cervix induce release of oxytocin from the posterior pituitary gland of the mother in a pulsatile manner. The uterine endometrium is the primary source of the prostaglandin $F_{2\alpha}$ that acts on the myometrium and cervix to stimulate contractions. As noted in **Fig. 1**, relaxin softens and increases the distensibility of the pelvic ligaments and dilation of the cervix forming a passageway sufficient for delivery of the fetus. An increase in concentrations of oxytocin and prostaglandins in maternal blood, along with formation of gap junctions between smooth muscle cells of the uterine myometrium induce increasingly powerful contractions of the uterine myometrium that expel the fetus and placenta into the extra-uterine environment.

(Ferguson reflex) which causes pulsatile release of PGF from the uterine epithelia that is luteolytic and causes regression of the CL and their secretion of P4. So, cortisol changes the sex hormone ratio from high progesterone and low estradiol during pregnancy to high estradiol and low progesterone during parturition.

The decreasing concentrations of progesterone and increasing concentrations of estradiol in the ewe leads to the formation of gap junctions (known as connexin 43) between smooth muscle cells of the uterine myometrium (see **Fig. 2**). The gap junctions allow the smooth muscle cells to communicate with each other to contract and relax in unison. Visualize that early in parturition there are few gap junctions so contractions are weak and infrequent, but progressive increases in numbers of gap junctions allow strengthening of contractions at more frequent intervals as more and more smooth muscle cells contract and relax in unison. During this time in the peri-parturient period, oxytocin is being released in greater amounts with strength and frequency of contractions because the fetus is putting more pressure on the cervix (Ferguson reflex) at increasingly frequent intervals. Finally, uterine myometrial contractions are sufficient to expel the fetus and then the placenta from the uterus, through the cervix and vagina to the external environment. PGF is also acting with oxytocin to stimulate contractions of the uterine myometrium.

Relaxin is a hormone produced by large luteal cells of the corpus luteum of pigs, the placenta and corpus luteum of cow and placenta of the mare. Relaxin interacts with other hormones including estradiol, PGF and oxytocin to cause relaxation and dilation of the cervix and pelvic ligaments. Relaxin increases keratin sulfate and decreases dermatin sulfate in cervical collagen. With loss of dermatin sulfate there is a decrease in cross-linking of collagen fibers which increases distensibility of the cervical collagen and the diameter of the lumen of the cervix.

Epinephrine stimulates synthesis and cortisol induces secretion of surfactant by epithelial cells of the fetal lungs which is critical for maturation and function of the lungs to ensure respiration and survival of the offspring.

Glossary

Active space The active space is the calculated volume of water (in the case of fish) in which a given odorant, including pheromones, is above the concentration at which it can be detected by the olfactory system. It depends primarily on the release rate of, and the olfactory sensitivity to, that odorant; a potent odorant with a high release rate will have a correspondingly large active space. Clearly, in the natural environment, the active space will also depend on water movement (e.g., river or tidal flow), diffusion speed (depending on molecular weight and temperature) and degradation rate.

Bile acids and alcohols Bile salts are steroidal compounds produced by the liver, and secreted into the intestinal lumen, *via* the gall bladder, where they aid digestion by emulsifying lipids. Most are reabsorbed during intestinal transit, but a fraction is excreted with the feces. They are potent odorants in fish, but only in the sea lamprey has their role as pheromones been clearly established.

Chemical communication Broadly, chemical communication can be defined as the use of chemicals as signals or cues in intra-specific communication. It includes pheromones, wherein the response is innate (does not require learning), but also kin- or individual recognition, which may be learned.

Hormone Classically, a hormone is a chemical compound released by one tissue or organ within the body, and carried *via* the circulatory system to a distant 'target organ' where it has a physiological effect ('endocrine'). Some hormones also act locally ('paracrine') or even on the same cells that produce them ('autocrine'), without the involvement of the circulatory system. This is a functional biological definition; hormones are of many different chemical classes (e.g., steroids and polypeptides). Some hormones, and/or their metabolites (but far from all), may also act as pheromones; these are called 'hormonal pheromones'.

Odorant and odor An odorant is simply any substance that is detected by the olfactory system (the chemosensory system of cranial nerve I in vertebrates). It may – or may not – be a pheromone. An odor, however, is a complex mixture of odorants typical of a habitat, species or even an individual (a 'signature mixture' in this case).

Pheromone Pheromones are "...substances which are secreted to the outside by an individual and received by a second individual of the same species, in which they release a specific reaction, for example, a definite behavior or a developmental process". They require no previous experience or learning. This is a functional biological definition; it does delineate the types of compound a pheromone may be. In fact, many pheromones are mixtures of different compounds.

Prostaglandin Prostaglandins are lipid derivatives *via* arachidonic acid with 20 carbon atoms (including a 5-carbon ring) which act as hormones, particularly as paracrine or autocrine factors, in many tissues of vertebrates. Notably, some prostaglandins also act as pheromones in some species of fish (e.g., Fig. 1(A) (ii)).

Steroid A steroid is an organic compound with the four carbon ring (three cyclohexane rings and one cyclopentane ring) core structure (e.g., 17,20 β -P, Fig. 1(A) (i)). This is a structural chemical definition; many (but not all) steroids may be hormones, and some (but far from all) steroids are pheromones (in some species).

Introduction

Fish are aquatic, non-tetrapod vertebrates; not a strictly phylogenetic definition, true, but one with which most are familiar. As fish live in water, this has many consequences for almost every aspect of their physiology; their olfactory and chemical communication systems are no exception. Firstly, for a given compound to act as a potential odorant in fish it must be water-soluble; for a terrestrial vertebrate, it must be both water-soluble and volatile. This means that fish odorants are often different types of compounds from those of terrestrial animals; this is true for pheromones, too. Secondly, aquatic environments differ markedly in their physico-chemical characteristics from terrestrial environments. In a river, for example, the water flow renders chemical territorial marking, used by many mammals, ineffective. Conversely, this reliable unidirectional flow makes long-range migratory cues more viable (see [Section Sea Lamprey](#)). Aquatic environments may often be turbid, turbulent and/or dark. Therefore, chemical signals – such as pheromones – may be more reliable, or more easily discerned, than visual or auditory cues. However, whatever their reproductive strategy or habitat, most fish species do not rely on one particular mode of communication, but use a multi-modal mixture of visual (e.g., vivid color patterns), behavioral (e.g., courtship displays), auditory and chemical cues,

Fig. 1 Some examples of reproductive pheromones identified in teleosts. (A) Goldfish (*Carassius auratus*) female pre-ovulatory pheromone 17 α ,20 β -dihydroxy-4-pregnen-3-one (i), wherein the group at R can be -H, -glucuronate or -sulfate, and (ii) post-ovulatory pheromone prostaglandin F_{2 α} . (B) Mozambique tilapia (*Oreochromis mossambicus*) male urinary pheromone 5 β -pregnane-3 α ,17 α ,20 β -triol-3-glucuronate. (C) Masu salmon (*Oncorhynchus masou*) female urinary pheromone L-kynurenine (2-amino-4-(2-aminophenyl)-4-oxobutonic acid). (D) Sea lamprey (*Petromyzon marinus*) spermiating male pheromone 17 α ,12 α ,24-trihydroxy-5 α -cholan-3-one 24-sulfate (3-keto-petromyzonol sulfate or 3kPZS). In each case, it is likely that other components remain to be identified.

including pheromones, to communicate. Nevertheless, to almost exclusively audio-visual animals such as ourselves, the extent to which other animals communicate using odors and pheromones is not always obvious, either at a conceptual or sensory level. As a result, the importance of chemical communication is often sadly over-looked or under-estimated; this is as true for fish as other (non-human) animals.

Fish form the largest most diverse class of vertebrates and, as such, show a wide range of reproductive strategies in diverse habitats. However, most (but not all) are external fertilizers; hence, many mechanisms have evolved to ensure that eggs and sperm are released – and are ready to be released – at the same time to maximize fertilization rates and reproductive success. Pheromones, and other chemical cues, are an important – but not the only – part of this process. Such cues may also play important roles in related processes, such as mate-choice, individual recognition and migration.

Functions of Reproductive Pheromones in Fish

As most fish are external fertilizers, it is vital for reproductive success that sperm and eggs are released at the same time and place. Two key roles for reproductive pheromones are therefore, firstly, allowing males and females to find each-other (and recognize each-other as such) and, secondly, ensuring that they reach spawning readiness at the same time. The relative importance of each clearly depends on both reproductive strategy and habitat; schooling fish, for example, are continually surrounded by conspecifics, so finding each-other is not an issue. However, pheromones and other chemical cues may play a role in mate selection in such fish; females may recognize more dominant males through their pheromone release and choose to mate selectively with those. Synchrony can be ensured by either sex recognizing physiological indicators of maturity in the other. Those hormones responsible for stimulating gamete maturation, such as the maturation-inducing steroid (17 α ,20 β -dihydroxy-4-pregnen-3-one) and

prostaglandins in females, and androgens such as 11-ketotestosterone in males, are obvious chemical indicators, and this has given rise to the concept of 'hormonal pheromones'; the goldfish (see below) is a good example of this. However, this is far from universal; the female reproductive pheromone of masu salmon, for example, is an amino-acid derivative with no obvious role in reproductive physiology (see below).

Sites of Synthesis and Routes of Release

Reproductive steroid pheromones are mainly synthesized in the gonads; androgens by the cells of Leydig, and estrogens by the theca interna and granulosa cells of the ovaries. However, many hormonal steroids are physiologically 'deactivated' by conjugation; enzymatic addition of a glucuronate or sulfate group (usually to carbon 3 or 17 of the steroid core). This has three major effects: the conjugated steroid can no longer bind to its receptor (and is thereby unable to produce its physiological action); it cannot bind to its plasma binding protein (so can pass into the urine); and it is much more water-soluble. The latter two may promote its functionality as a pheromone, and many fish have evolved olfactory sensitivity to conjugated steroids, as well as – or even instead of – the free form. As the dynamics of release of these metabolites may be different from the parent steroid, they may also take on subtly different pheromonal roles (see [Section Goldfish](#)).

Fish are in intimate contact with their medium; water. Therefore, pheromones could potentially be released over any epithelium; across the gills, skin or *via* the urine or feces, or even with the gametes themselves. There is evidence that fish may use all of these. Free steroid pheromones may simply diffuse over the gills, or be actively excreted by specialized cells (e.g., sea lamprey). The skin mucus may also act as a route of release for pheromones, or other chemical cues involved in mate-choice or kin-recognition, such as the major histocompatibility complex (MHC), although the chemical types involved have not been identified. Urine, as in mammals, has been clearly identified as the vehicle of several reproductive pheromones (e.g., goldfish, tilapia and masu salmon). However, for osmoregulatory reasons, marine fish do not produce as much urine as their freshwater counterparts; in this case, feces may also act as a vehicle for pheromone release. Fish certainly have high olfactory sensitivity to feces! In some species, the ovarian and/or seminal fluids themselves may contain pheromones (e.g., the herring; [Carolsfeld et al., 1997](#)). Other fish may produce pheromones in specialized glands, such as the anal glands of blennies (e.g., [Serrano et al., 2008](#)), which are released directly to the water, or the testicular glands, seminal vesicles and blind pouches of many fish, where steroid conjugation is thought to occur ([Lambert and Resink, 1991](#)).

Detection of Pheromones: Olfaction

Fish live in water; one consequence of this is that a given compound only needs to be water soluble to have the potential to act as an odorant in fish whereas, in terrestrial animals (with some exceptions), it must be both water-soluble and volatile. Fish odorants are, therefore, often chemically distinct from tetrapod odorants; this includes pheromones. Unlike tetrapods, fish do not have an accessory olfactory system or vomero-nasal organ (VNO); pheromones are detected by the main (only) olfactory system. Fish have three types of olfactory receptor neurons (ORNs): ciliated, microvillous and crypt cells. Some circumstantial evidence suggests that pheromones are detected by crypt cells, but this remains controversial.

In vertebrates, fish included, olfactory receptors, including those for pheromones, are thought to be G protein coupled receptors (GPCRs). Recently, for example, a receptor for a female pheromone, prostaglandin $F_{2\alpha}$, was identified and cloned in zebrafish ([Yabuki et al., 2016](#)). However, for the majority of fish, the pairing of pheromone with its receptor is a field of active research.

Most reproductive pheromones are thought to exert their physiological effects *via* the hypothalamus-pituitary-gonad (HPG) axis, primarily through the release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from the pituitary. The olfactory receptor neurons detecting pheromones converge on one, of few glomeruli in the olfactory bulb (the part of the central nervous system responsible for the first-order processing of olfactory input), and then second-order neurons send axons *via* the medial olfactory tracts to the hypothalamus; a clear case of 'hard wiring'. However, how these same pheromones exert their effects on behavior is less clear; possibly by involving the 'social brain network'. More research is needed to resolve this.

Model Species

Goldfish

The goldfish (*Carassius auratus*) is the best studied fish with respect to reproductive pheromones ([Dulka et al., 1987](#)). Goldfish belong to the family Cyprinidae which also includes the widespread research model species, the zebrafish (*Danio rerio*), although the chemical identities and biological roles of zebrafish reproductive pheromones are much less clear. Although Cyprinidae is the largest teleost family, it is exclusively fresh-water; most cyprinids, including the goldfish, are synchronous 'scramble competition' spawners wherein a post-ovulated female (i.e., a female ready to spawn) is pursued by several males. The males nudge the belly of the female, stimulating her to release her eggs onto underwater vegetation where they are fertilized by sperm released simultaneously by the males. Goldfish use steroids and prostaglandins as pheromones ([Dulka et al., 1987](#); [Sorensen et al., 1988](#)). However, the involvement of pheromones begins the night before; the ovaries produce a steroid hormone $17\alpha,20\beta$ -dihydroxy-4-pregnen-3-one (' $17,20\beta$ -P'; [Fig. 1\(A\)](#)) that induces final maturation of the oocytes, ready for spawning

the next day. Somewhat unusually for a steroid hormone, $17,20\beta\text{-P}$ does not bind to a high affinity binding protein in the blood, but remains free to be released into the surrounding water, probably over the gills. It is then detected by the olfactory system of the males, at concentrations as low as 10^{-12} M, and this induces a release of luteinizing hormone (LH) from the males' pituitary gland which, in turn, stimulates the production of milt and sperm in the testes. Conjugated metabolites of $17,20\beta\text{-P}$, its sulfate and glucuronate forms (Fig. 1(A)) – hormonally inactive but pheromonally highly active, and released slightly later – are also detected by the males at pico-molar concentrations and have slightly different effects on male physiology and behavior (Poling *et al.*, 2001). The following morning, once the female has ovulated (i.e., the mature oocytes have been released from the ovaries into the ovarian ducts prior to release), the hormone responsible for this release, prostaglandin $F_{2\alpha}$ ($\text{PGF}_{2\alpha}$) and its metabolite $15\text{keto-PGF}_{2\alpha}$ are also released to the water, probably *via* the urine, where they stimulate the chasing and nudging reproductive behavior of the males and, ultimately, synchronous release of sperm and ova. Another steroid, androstenedione released by the males, increases aggression and competition among males while reducing their rivals' responsiveness to female pheromones (Sorensen *et al.*, 2005b).

Following these discoveries, many other cyprinids were found to both release, and have high olfactory sensitivity to, $17,20\beta\text{-P}$, $\text{PGF}_{2\alpha}$ and their metabolites. It is possible, likely even, that these compounds play similar pheromonal roles, given that most cyprinids have a similar reproductive strategy to the goldfish. However, this raises an intriguing and, as yet, unanswered question; how is species-specificity conferred to the pheromonal message? $17,20\beta\text{-P}$ or $\text{PGF}_{2\alpha}$ released by a carp or tench, for example (sympatric congeners of the goldfish), must smell the same as that released by a goldfish. The answer may lie in specific ratios of the compounds involved (e.g., as in insects), perhaps including other, unidentified, odorants. Conversely, the natural occurrence of many hybrids may suggest that pheromones are not completely species-specific, and that context, or other cues, are more important in conferring species-specificity. However, it will be clear from the following that other types of fish use very different chemicals as pheromones.

Masu Salmon

Although many salmonids spend significant parts of their lives in seawater, all spawn in freshwater. It is well known that many salmonids return to their natal stream to spawn, and that olfaction plays a vital role in this homing behavior. However interesting, this lies beyond the scope of a review of reproductive pheromones. Nevertheless, the masu salmon (*Oncorhynchus masou*) is one salmonid in which a female reproductive pheromone, an amino acid derivative, L-kynurenine (Fig. 1(C)) has been identified (Yambe *et al.*, 2006). Researchers noticed an intense blue fluorescent spot stained with ninhydrin reagent (which specifically stains amino acids) on TLC plates of ovulated female urine that was not present in immature female urine, or male urine. This was subsequently identified as 2-amino-4-(2-aminophenyl)-4-oxobutonic acid (christened 'L-kynurenine'), and was shown to attract mature males, but not immature males or females. Furthermore, the olfactory system of mature males was 1000 times more sensitive to L-kynurenine than immature males, and even more so than females, with a threshold of detection of 10^{-14} M. A calculated release rate of $0.4 \mu\text{moles h}^{-1} \text{ female}^{-1}$ therefore gives an active space of $40 \times 10^6 \text{ L h}^{-1} \text{ female}^{-1}$! This is more than sufficient to account for attraction in the mountain streams in which they spawn.

Although L-kynurenine is a major metabolite of L-tryptophan in vertebrates, and amino acids are potent odorants for fish, its link with reproduction is not as obvious as, for example, $17,20\beta\text{-P}$. The authors suggest that its metabolism is under the same hormonal regulation as oocyte maturation; however, urinary concentrations in other salmonids are much lower (around 1%). This therefore begs the question as to what other salmonids may be using as reproductive pheromones.

Tilapia

The Mozambique tilapia (*Oreochromis mossambicus*) and its close relative, the Nile tilapia (*O. niloticus*) are enormously important in aquaculture and, consequently, as invasive species world-wide. They are cichlids (family: Cichlidae), a scientifically outstanding taxon due to their complex social behaviors, including parental care, coloration and the bewilderingly rapid speciation seen in the African Rift Lakes cichlids. Despite, or perhaps because of, cichlids' bright coloration and behavioral displays, chemical communication has only been investigated in any depth in the Mozambique tilapia. Mozambique and Nile tilapia are maternal mouth-brooding, lek-breeding African cichlids. Males establish a hierarchy within the 'lek' (a term borrowed from ornithologists meaning a display area for courtship and breeding), wherein each male digs a simple nest in the sand or gravel bottom, with the more dominant males occupying the lek's center, and the submissive males towards the periphery. Females, when ready to spawn, approach the lek; the males express instantly recognizable courtship behavior towards the female, including characteristic black (Mozambique tilapia) or white (Nile tilapia) coloration, circling the female, 'grunting' (inaudibly, to humans at least) and trembling. Less obviously, Mozambique tilapia males also dramatically increase their urination rate (Fig. 2); dominant males, in particular, are able to store large volumes of urine in their bladder, which they release both during courtship and during aggressive displays against rival males. As the male circles the female, she is effectively surrounded by a cloud of male urine; this urine contains a steroid glucuronate, $5\beta\text{-pregnane-3}\alpha,17\alpha,20\beta\text{-triol-3}\alpha\text{-glucuronate}$ (and, to a lesser extent, its $20\alpha\text{-epimer}$; Keller-Costa *et al.*, 2014; Fig. 1(B)). This steroid pheromone, present at much higher concentrations in dominant male urine (up to 0.5 mM) than that of subordinates, dramatically increases the female's production of $17,20\beta\text{-P}$, the maturation inducing steroid (see Section Goldfish), thus insuring that a sub-set of her oocytes become mature at the correct moment (tilapia, unlike goldfish, are 'asynchronous'; not all oocytes mature at the same time). The female then chooses a male

Fig. 2 The male reproductive pheromone of Mozambique tilapia. While performing his highly visible (and audible – at least to his intended audience) courtship display towards the female, the male releases many pulses of urine containing the pheromone 5β-pregnane-3α,17α,20β-triol-3-glucuronate (and its 20α epimer); dominant males have much higher urinary concentrations than subordinates. After smelling this, increased synthesis of the maturation-inducing steroid, 17,20β-P, is stimulated in the female. This ensures the final maturation of a cohort of ova, which she then releases to be fertilized by the male. Taken, with permission, from Keller-Costa, T., Canário, A.V.M., Hubbard, P.C., 2015. Chemical communication in cichlids: A mini-review. *General and Comparative Endocrinology* 221, 64–74.

with which to spawn; it is likely that this choice is made at least in part on the smell of his urine, including the perceived concentration of pheromone. After spawning, the female picks up the fertilized eggs in her mouth and moves away (often actively chased by the male) to brood them elsewhere. Although 17,20β-P acts as the maturation-inducing steroid in tilapia, as in goldfish, the tilapia cannot smell it, ruling out any pheromonal role for this steroid in this species. Nevertheless, males are still able to assess the reproductive status of the female through olfaction (possibly involving another steroid glucuronate, estradiol-3-glucuronate), and will only release urine towards a female who smells 'ready'. Although investigated in less detail, it seems likely that the Nile tilapia uses the same urinary steroids as reproductive pheromones, as they are present in male urine, and both sexes have similar olfactory sensitivity to them. Although the olfactory sensitivity of the tilapia to these steroids (threshold about 10^{-10} M) is much less than the examples from goldfish, masu salmon and sea lamprey, and the active space correspondingly lower, this is not a problem as the interactions take place at close quarters.

As previously mentioned, male Mozambique tilapia also use urine to signal to rival males during aggressive displays. These encounters are more likely to escalate to violent fights if the males are unable to smell one-another's urine, and thereby assess their relative ranking, suggesting the existence of a 'dominance' pheromone. However, the chemical identity of this pheromone has yet to be established.

Sea Lamprey

Unlike the other species discussed here, lampreys are not teleosts (bony fish), but agnathans; primitive jawless fish. Despite their name, sea lampreys (*Petromyzon marinus*) spawn in freshwater. Sadly threatened in their natural habitat (the north Atlantic Ocean and associated rivers), they have become a nuisance invasive species in the Great Lakes of North America, where they live their whole life-cycle in fresh-water, parasitizing many native species and thereby causing massive declines in their stocks. This has stimulated much research into possible methods of population control; one example is the use of pheromone traps, highly effective for pest insects. Obviously, this has necessitated the isolation and identification of the pheromones involved. Bile acids (a type of steroid synthesized by the liver and secreted into the intestine), principally petromyzonamine disulfate, from larval sea lamprey attract adult males when they are ready to spawn (Sorensen *et al.*, 2005a). It is likely that the presence of sufficient larvae to produce a detectable scent in the water entering the sea (or lake, in this case) is a reliable indicator that the stream is a suitable habitat for lamprey larvae. This is not 'homing' (as in the case of salmon), because the adults do not necessarily return to their natal stream, but

is a good example of a migratory pheromone. However, the true reproductive pheromone is a mixture of bile acids, including petromyzon sulfate (Fig. 1(D)), released by spermiating males. The males, lured by the larval migratory pheromone, arrive at the spawning sites before the females, to dig a crude nest in the gravel. The ripe females are then attracted by the mixture of bile acids released by the males (Li *et al.*, 2002), and join them in their nests where spawning occurs. However, in contrast to the other species discussed here, this pheromone is not released *via* the urine, but by the active secretion of specialized cells in the gills (Siefkes *et al.*, 2003). Also contrasting with the goldfish, at least, the gonads are an unlikely source of the bile acid pheromones; bile acids are synthesized by the liver. Although the sea lamprey is the only fish wherein bile acids have been shown to play pheromonal roles, fish in general have high and broad olfactory sensitivity to this class of compound. Thus, it is possible that bile salts also act as pheromones in other species; in the European eel, for example, the type of bile acid produced by the liver depends both on sex and sexual maturity.

Field tests with 'pheromone traps' baited with artificial mixtures of bile acids, based on these discoveries, have never been as effective as traps baited with the natural pheromone (i.e., spermiating males) in luring ripe female sea lamprey to their doom, suggesting that there are components to this pheromone yet to be discovered. However, such experiments at least provide 'proof of principal' for the use of pheromone traps for control of fish populations in a highly specific and environmentally harmless manner.

Conclusions

It should be clear from the above that the diversity of reproductive strategies in fish is matched by an equal diversity in their reproductive pheromonal systems. This is in marked contrast to the conservatism (evolutionarily speaking) of their internal regulatory mechanisms, the reproductive hormones, which have similar chemical structures and physiological functions across the vertebrates. Some fish, such as the goldfish, have expanded the roles of these internal regulators to that of reproductive pheromones, while others, such as the sea lamprey, have commandeered a class of compound – bile acids, with no apparent internal link to reproduction – as pheromones. However, what is also clear is that much remains to be discovered. How much 'overlap' is there in the types of chemicals used as pheromones? How are these related to phylogeny, or biological roles? How is species-specificity conferred to the pheromonal message? And how do marine fish use reproductive pheromones? These are all areas of active research.

Glossary

Aggregation pheromone One sex produces the signal, and both sexes are attracted to the signal.

Anosmia Inability to detect or perceive a chemical compound.

Detection Identification of the presence of a signal.

Hormesis Dose-response phenomenon whereby a low dose (e.g. of insecticides) gives a high behavioral response, while at higher doses the response is reduced.

Natural selection Selection exerted by other species (biotic factors) or by abiotic factors (temperature, light).

Perception Detection of a signal including the interpretation of the signal after integration in the brain center.

Pheromone Infochemical that conveys information between individuals of the same species.

Pheromone component Chemical that has been behaviorally tested and confirmed to attract potential mating partners, in contrast to a pheromone compound, which has been chemically identified to be in the pheromone blend but not confirmed to be behaviorally important for attraction.

Plasticity Variation within individuals during development, sexual maturation, aging, or upon experience.

Reception Detection of a signal at the receptor level.

Sex pheromone Attractant between the sexes (one sex produces and emits the signal, and the other sex from the same species perceives and responds/is attracted to the signal).

Sexual selection Selection exerted by potential or rival mating partners within a species.

What are Insect Sex Pheromones?

Sex pheromones are ubiquitous in the animal kingdom and present in all insect orders (Gomez-Diaz and Benton, 2013). Since the first identification of the sex pheromone in the silkworm *Bombyx mori* in 1959, the sex pheromones of more than 1500 insect species have been identified (Pherobase.com). Generally, sex pheromones consist of a blend of at least two chemical components. Species or race specificity is ensured by the blend composition and the ratios of the components. The most famous example is the European corn borer, *Ostrinia nubilalis*, which consists of two pheromone races that have opposite ratios of the same two pheromone components.

There is enormous diversity in the chemical nature of sex pheromones, as they can consist of saturated or unsaturated hydrocarbon chain carrying an acetate, alcohol or aldehyde function (in most moths), polyenic hydrocarbons, methyl-branched hydrocarbons (e.g. in Lepidoptera and Coleoptera), epoxides, ketones (e.g. in some Coleoptera), terpenes (e.g. in beetles) and terpenoids (e.g. in some geometrids and pyralids), iridoids (e.g. in aphids), as well as alkaloids (e.g. in Scarabidae) (Howard and Blomquist, 2005; Hanks and Millar, 2016; Allison and Cardé, 2016; Jurenka, 2004; Dewhirst *et al.*, 2010; Yew and Chung, 2015). Representative structures of insect sex attractants are illustrated in Fig. 1, including those of moths, honeybee, cockroach, bug, and fruit fly.

Sex pheromones can be short(er) carbon chain volatiles that attract potential mating partners from a longer or shorter distance, or long(er) carbon chain cuticular hydrocarbons (CHCs) that are used to identify potential mating partners or rivals upon contact. Volatile and contact chemical cues may be integrated to reinforce or refine selection of the right mating partner. In species with additional cues, such as visual and acoustic cues, or species-specific movements, genitalia incompatibility, spatial and seasonal separation of populations, and diel separation of pheromone release, sex pheromones may consist of more ubiquitous compounds. The most striking example is found in aphids, where the sex pheromone of all species consist of nepetalactone and nepetalactol, and the species-specificity mostly comes from the combination of sex pheromone with other environmental cues (Dewhirst *et al.*, 2010). The amount of pheromone that is secreted from or is present in a pheromone-producing gland also varies enormously with species and, to some extent, behavioral function. Sex-attractant pheromones may be present in microgram, nanogram, and even picogram quantities per individual.

Fig. 1 Representative insect sex pheromone molecules illustrating the diversity of chemical structures.

Sex pheromones are not only diverse in terms of amounts, range or ratios of different compounds, but also in terms of enantiomers with opposing, inhibitory effects (Yew and Chung, 2015). For example, closely related species that occur sympatrically and have a similar sex pheromone may avoid hybridization by having different ratios of the same pheromone components or by having additional minor pheromone components that inhibits the attraction of the other species. One example for such behavioral inhibition is found in the gypsy moth (*Lymantria dispar*) and the nun moths (*L. monacha*) that share (+)-disparlure as attractant and live in sympatry in parts of Europe. In addition to (+)-disparlure, the female nun moth produces (–)-disparlure, that inhibits the attraction of male gypsy moths, thus ensuring species isolation. The use of such enantiomers or diastereoisomers in pheromone blends is quite common, especially in species where mate finding relies mostly on sex pheromone communication.

Who Produces Sex Pheromones?

Which sex is the signaler and which sex is the responder varies between insect orders, as well as on the range at which potential mating partners are attracted. The most typical example is found in moths: in most species females adopt a characteristic calling

behavior by which they extrude a pheromone gland for emission of a long-range sex pheromone in the air to attract males from a distance. In some lepidopteran species, such as the arctiid moth *Utetheisa ornatrix*, females group together for calling in chorus, which synchronizes and intensifies their signaling, thus favoring attraction. Receiver males fly upwind to the female with a stereotyped zig-zag behavior. Once in the vicinity of the female, males start courtship and in some species produce a close-range sex pheromone that may play a role in female choice. More rarely, as in the sugarcane borer *Eldana saccharina*, male moths emit a long distance pheromone from a gland/hair pencils on their abdomen, or from hair tufts on their wings, so-called coremata. In beetles, flies and several Hemiptera (true bugs), males attract females mostly at close range or upon contact. Tephritid flies display a lek mating system, where males aggregate and emit different visual, acoustic and chemical signals to attract females. Arriving female flies assess the multimodal calling behavior of a number of calling males before selecting a mate among the available ones.

Where are Sex Pheromones Produced?

The locations of the glands or tissues responsible for sex pheromone production are very diverse. Volatile sex pheromones are generally produced in specific glands, such as sex pheromone glands located at the tip of the abdomen in female moths, hair pencils/hair pockets (coremata) in male moths and butterflies, or epidermal glands located under the abdominal tergites of cockroaches. CHCs are produced in oenocytes, which are secretory cells inside the hemolymph (which can be close to epidermis or scattered throughout fat body). *Ips* beetles produce their sex pheromone in the hindgut, the signal being released with the frass. Tephritid flies produce pheromones in salivary and anal glands. In aphids, mature sexual females (oviparae) release a sex pheromone from scent plaques on their hind tibiae which attracts conspecific males (Dewhurst *et al.*, 2010).

Sex pheromones can be produced *de novo* or may be sequestered from plants (Jurenka, 2004). When produced *de novo*, the sex pheromones are generally derivatives from fatty acids (moth sex pheromones and CHCs). In some cases, microbes or symbionts participate in pheromone biosynthesis. For instance, gut microbiota may participate in the verbanone pheromone production in bark beetles. How aphids produce their sex pheromone components (nepetalactone and nepetalactol) is unknown, possibly nepetalactol is produced from a glycoside precursor, a proportion of which is sequentially oxidized to nepetalactone (Dewhurst *et al.*, 2010).

Some insects sequester or acquire host plant compounds and use them as sex pheromones or sex pheromone precursors. The most famous example is the arctiid butterfly *Utetheisa ornatrix* (Arctiidae), whose male courtship pheromone derives from pyrrolizidine alkaloids (PAs), which are ingested at the larval stage from the host plant *Crotalaria spectabilis*. Males also transfer PAs to females during mating as a nuptial gift, which females subsequently use to coat their oviposited eggs, which are then protected against predators (Eisner, 2003). In other arctiids, most Dancinae and Ithomiinae butterflies, males also obtain PAs from plants and use them as pheromone precursors. *Cysseps fulvicollis* (Arctiidae) males produce hydroxydanaidal from PAs of dead and damaged plants, and release it as a sex attractant. Host plant volatile emissions can also have an indirect impact on insect sex pheromone communication, for instance in *Helicoverpa* species where host plant volatiles induce female calling behavior. In some *Ips* beetles, exposure to plant volatile myrcene increases the amounts of ipsenol and ipsdienol pheromones in male hindgut tissues. On the receiver side, sex pheromone detection and processing has been also shown to be modulated by the presence of plant volatiles: chemicals from host plants often synergistically enhance the response of an insect to the sex pheromone, improving temporal resolution of pulsed pheromone signals, while some others can have inhibitory or repellent effects that interrupt the response.

When are Sex Pheromones Produced?

Upon Sexual Maturation

Pheromone emission and sensitivity usually coincide with sexual maturity. In most moth species, females and males start to become sexually active 1–2 days after emergence. In general, pheromone glands contain very low levels of pheromone on the first night after emergence, which then increases sharply in subsequent nights. When females get older or after mating, sex pheromone levels may decline again, at least for a short or a long period. In many moth species, female sex pheromone production follows a diel rhythm that is regulated by the nightly release of the pheromone biosynthesis activating neuropeptide (PBAN) from the subesophageal ganglion (Jurenka, 2004). In some moth species, previously synthesized fatty acids are stored as triglycerides in lipid droplets and mobilized by phosphorylation, while in other species, such as *Trichoplusia ni*, pheromone is continuously produced and not regulated by PBAN. In long-lived insects with multiple reproductive cycles, such as cockroaches, beetles and flies, pheromone production is regulated by juvenile hormone (JH) and ecdysone (Jurenka, 2004). For example, in beetles JH regulates pheromone production of both fatty acid and isoprenoid biosynthetic pathways, while JH in turn is regulated by environmental and physiological factors. In bark beetles, feeding on a new host tree elevates JH titers by stimulating activity of the corpus allatum, the endocrine gland that produces JH. In Diptera, ecdysone instead of JH stimulates egg maturation as well as sex pheromone production, most likely by regulating the fatty acyl-CoA elongases (Jurenka, 2004).

At Specific Times of the Day

Many moth species show specific daily activity rhythms in their sexual activities, some species being sexually active in the day, some early at night, while others are sexually active late at night. This differentiation has been suggested to have arisen to minimize

communication interference between closely related species, as co-occurring and closely related species with overlapping sex pheromone blends show a temporal differentiation in their daily sexual activities. For example, in the Mojave Desert of California *Hemileuca electra* calls from mid-morning to early afternoon; the closely related species *H. burnsi*, which shares pheromone components with *H. electra*, calls from midafternoon to dusk. Without exclusive times for mating activities, these species would cross-attract.

At Specific Times in the Year

Many insect species are sexually active only at specific times of the year, usually in the summer time. When the summer period is long (at lower latitudes), multiple generations may develop in one season, while at higher latitudes only one generation may develop. This is the case for example in the European corn borer, where populations near the Canadian border are univoltine, while more southern populations are bi- or even trivoltine, which genetically isolates these populations. Species may also be sexually active early or late in the season. In migrating species, such as the monarch butterfly *Danaus plexippus* and the noctuid moth *Helicoverpa armigera*, adults become sexually active only after arriving at their breeding site.

Variation and Plasticity in Insect Sex Pheromones

Geographic variation in sexual communication signals and responses has been found in many species, even when sex pheromones are mainly used as species-specific recognition cues, which inhibits variation and promotes retention of the species-specific blend (Allison and Cardé, 2016). This already indicates that environmental cues influence sexual communication; both the signal and response can be affected by both abiotic and biotic factors, such as photoperiod, temperature, the occurrence of closely related species that may interfere in the sexual communication when the sexual signals are very similar, and presence of predators and parasitoids that may home in on the sex pheromone to find their prey (Fig. 2). Since many female moths produce their sex pheromone *de novo* every night, females may adjust their pheromone blend depending on the current local environmental conditions.

The sex pheromone signal may vary in quantity as well as in quality. The quantity is mainly affected by host plant volatiles, nutrition and temperature, while the quality can be affected by immune defence responses and experience. For example, when *Heliothis subflexa* females emerged and remained in the odour of the closely related species *H. virescens* for three days, females contained significantly more of a sex pheromone component that not only attracts conspecific males but also inhibits the attraction of *H. virescens* males. Thus, early-adult experience of different chemical environments affects the sex pheromone

Fig. 2 Factors that may affect sex pheromone communication in moths.

composition in *H. subflexa* females. In aphids, the ratio between the two pheromone components nepalactone and nepelactol varies depending on the age of the females, increasing after maturation and then decreasing at later ages, which may be a symptom of senescence (Dewhurst *et al.*, 2010). In the cockroach *Nauphoeta cinerea*, the male sex pheromone varies depending on the carbohydrate intake, and a higher intake increases the male attractiveness, thus increasing their reproductive fitness. Changes in CHC composition have been found in the housefly *Musca domestica*, where the melting temperature of the surface lipids isolated from female houseflies decreased from 39°C to 35°C as the females attained sexual maturity and produced sex pheromone, whereas those prepared from males did not change with age.

The quality of the sex pheromone may also be affected by immune defence responses, as generally hypothesized by the Zahavi handicap principle (i.e., hypothesis proposed to explain how evolution may lead to “honest” or reliable signaling between animals which have an obvious motivation to bluff or deceive each other). The level of sexual attraction may signal the level and extent of health. However, if sexual attractiveness and immunity compete for the same resource pool, they may negatively affect each other. For example, the sex pheromone blend of *Heliothis virescens* females shifted towards an unattractive blend when females were infected with an entomopathogenic bacterium.

How are Sex Pheromones Perceived/Detected?

Mechanisms of Pheromone Detection in the Receiver

Volatile pheromones are detected by the olfactory organs of insects, the principal one being the antennae. These antennae harbour cuticular expansion called sensilla, many of which are dedicated to pheromone reception in the receiver sex (Fig. 3(A)). For instance, male silkmoth *Bombyx mori* antennae are covered by dizaines of thousands of pheromone sensitive sensilla. In addition, antennae may have a sophisticated shape, such as the pectinated antennae of the silkmoth that increase their surface to accommodate larger numbers of pheromone-sensitive sensilla. These sensilla usually house one or two olfactory receptor neurons (ORNs), which are bipolar cells that ensure the transformation of the chemical message into an electrical message that will be transmitted to the brain (Kaissling, 2014; Fig. 3(B)).

Pheromone-sensitive neurons usually respond to a single pheromone component, rarely two. This situation is clearly different from the responses of “generalist” ORNs that are usually activated by a family of related chemicals. The ORN dendrites extend in the sensillum lumen filled with the sensillum lymph, whereas their axons group together in antennal nerves that enter the antennal lobes (the primary processing center in the central nervous system) where they synapse with central neurons in glomerular structures. Axons of pheromone-sensitive neurons have a specific neural circuit as they project to a sexually dimorphic macroglomerular complex dedicated to pheromone signal integration. Pheromone information is relayed via antennal lobe

Fig. 3 Illustration of pheromone detection in moths. (A) Head of a moth with two antennae. Antennae carry cuticular expansions called sensilla, some of which are devoted to pheromone detection. (B) Pheromone sensitive sensilla usually house one to three olfactory receptor neurons (red) surrounded by accessory cells (green). The dendrite expands in the cuticular lymph while the axon goes to the central nervous system for signal integration. (C) Molecular mechanisms of pheromone reception. The pheromone molecule (orange) enters the sensillum via cuticular pores. It travels in the sensillum lymph bound by pheromone-binding proteins (PBPs) to the membrane bound pheromone receptor (PR). PR works together with a co-receptor (Orco) to transform the chemical signal into an electrical signal via ion channels opening. Modified from Kaissling, K.-E., 2004. Physiology of pheromone reception in insects (an example of moths). ANIR 6, 73–91.

projection neurons to both the mushroom bodies and the lateral protocerebrum. Understanding how the pheromone cues are converted *in fine* to the appropriate behavior is still a scientific challenge.

At the molecular level, the pheromone molecules enter the pheromone sensitive sensilla via cuticular pores. Most pheromones being hydrophobic, they are supposed to be solubilized by dedicated soluble proteins, the so-called pheromone-binding proteins, to cross the aqueous sensillum lymph and reach specific pheromone receptors (PRs) located in the dendritic membrane of the ORNs (Vogt, 2005; Fig. 3(C)). These PRs are part of the insect odorant receptor (OR) family, an unusual family of seven transmembrane domain ionotropic receptor proteins totally unrelated to mammal ORs. After pheromone interaction with its receptor, signal termination may be ensured by pheromone-degrading enzymes abundantly expressed in the sensillum lymph. A fast inactivation is indeed necessary for an efficient orientation behavior to the pheromone source. Although we still lack a consensus view on the exact function of each protein family, the occurrence of a diversity of members in each family accounts for their participation in the specificity of pheromone recognition. The combinatorial expression of these proteins within a sensillum may ensure the specificity, the sensitivity and the dynamic of the olfactory reception, defining the functional phenotypes of pheromone-sensitive neurons.

Most of the PRs functionally characterized to date – meaning their pheromone ligand is known – are from moths, and few others have been characterized in Diptera – mainly fruit fly–, Coleoptera – mainly Cerambycidae – and Hymenoptera. The general observation is that PRs tuned to the major pheromone components are usually very selective, like the ORNs that express them, while some others can recognize pheromone components from closely related species as well as behavioral antagonists (Montagné *et al.*, 2015; Zhang and Löfstedt, 2015).

Non-volatile close range pheromones are detected by contact chemodetection that involves taste structures such as the labellum or forelegs, for instance in the fruit fly. There, gustatory receptors (GRs) that are structurally related to ORs and/or two transmembrane domain Pickpocket (PKK) ion channels would ensure the signal recognition.

Who is the Receiver?

Because sex pheromone signaling is from one sex to the other, one would expect that only the opposite sex receives the emitted signal. Indeed, females of the silkmoth lack the specific receptor to the sex pheromone bombykol, they are thus anosmic to the pheromone they emit. However, females from other moth species express pheromone receptors as in males – although in a smaller amount – and autodetection by the signaler is frequently observed. The elicited behaviors are usually gender-specific: each sex exhibits a different behavior when exposed to the same cues, probably due to sexually dimorphic connectivity in higher-order neurons. In moths, while males would use the pheromone signal to detect an appropriate female, the female may detect its own pheromone to autoregulate its biosynthesis. Alternatively, detection of conspecific sex pheromone may allow evaluation of the local female density and thus the mating success probability. In the fruit fly, the male-specific sex pheromone cis-vaccenyl acetate (cVA) is detected by a pheromone receptor expressed in both male and female antennae. In males, cVA inhibits male–male courtship, while in the female it increases its sexual behavior.

Evolution of Pheromones and Their Role in Speciation

Insect sexual communication can be under different types of sexual and natural selection. Sexual selection may be exerted by the receiving sex when sex pheromones are used to choose among potential mating partners within a population (or species), or by the producing sex when mate competition occurs (Groot *et al.*, 2016). For example, in *Drosophila* flies and *Heliothis* moths, males perfume the females with their short-range sex pheromone, which inhibits the attraction of other, rival males. Natural selection can occur when other, predatory or parasitoid, species home in on the pheromone signal to locate their prey. A famous example is the bolas spider that can mimic the sex pheromone of different moth species. Natural selection can also occur when the pheromone has a dual function, which has been found to be the case in CHCs, as these also prevent insects from desiccation (Chung and Carroll, 2015). This has been illustrated in *Drosophila serrata* and *D. birchii* that co-occur in Australia and exhibit strong pre-mating isolation. *D. serrata* is a habitat generalist, with high amounts of methyl branched CHCs that prevent water loss and affect mating success, while *D. birchii* is a habitat specialist occurring in the humid rainforest, which is much less desiccation resistant, and produces only trace amounts of methyl branched CHCs that do not play a role in mating success.

When sex pheromones are subject to both sexual and natural selection, diversification of sex pheromones may be enhanced when both selection forces are in the same direction (as the example of CHCs). When sex pheromones are mainly used as species-recognition cues, i.e. to distinguish conspecific from closely related heterospecific individuals, and closely related species produce very similar sex pheromone blends that may only differ in the ratio of the different pheromone components, sex pheromones seem to be under stabilizing selection; For the signaler any deviation away from the mean lowers the probability of attracting the right (conspecific) mating partner. For the receiver, attraction to an off-blend can increase the chance of being attracted to another closely related species with a very similar sex pheromone. Counter-selection forces may occur when predators or parasitoids home in on the sex pheromone signals, which causes a trade-off between attraction to potential mating partners or to the enemy.

The use of sex pheromones in pest management may also cause selection towards alternatives sex pheromone blends (Witzgall *et al.*, 2008). For example, mating disruption is used in moth pest management: by saturating the air with synthetic sex pheromone lures, the males are unable to locate the females, which thus prevents matings. However, this may pose selection to both the

female signal and the male response to vary their sexual communication such that they will be able to find each other again. Such changes have for example been found in the summer fruit tortrix *Adoxophyes honmai*, where males did not respond to the common female pheromone blend anymore.

Pheromone Communication in a Changing World

Since pheromone signals and responses can be affected by many external biotic and abiotic factors (such as presence of plant volatile compounds, insect density, temperature, wind, humidity, pollution), global changes may also affect sex pheromone communication, either with direct effects on the insect physiology, or via modification of environmental factors that influence the pheromone communication. For example, as host plant volatile emissions have an impact on insect sex pheromone communication, one can expect temperature, CO₂ and ozone increases in the coming years to affect plant volatile emission and thus to impact the sex pheromone communication and by consequence the reproductive success of many insects.

Another interesting anthropomorphic impact is the effect of insecticides. Whereas the sex pheromone communication is generally altered when insects are exposed to insecticides, exposure to sublethal doses of some insecticides such as organochlorides, neonicotinoids or pyrethroids, has been shown to enhance reproduction abilities, a phenomenon called hormesis. Although neglected for long, insecticide-induced hormesis showing such a reversal of response between low and high doses of insecticides has been found in a number of species. The underlying mechanisms remain largely unknown, but the olfactory system appears to be affected and pheromone detection and associated behavior enhanced. For instance, chlordimeform treatment at low-dose induced a very high sensitivity to sex pheromone in the oriental fruit moth and the cabbage looper, and deltamethrin enhances the male response to pheromone in the cotton leafworm. Such phenomena may participate in pest insect resurgence.

Glossary

Chemosignal A chemical signal.

Countermarking behavior Behavior of males to deposit a scent mark adjacent to, or on top of an existing scent mark.

Formylated Addition of the formyl functional group to a molecule.

Freezing response Behavior in which an animal is completely immobile so as not to attract attention from a possible predator.

Genome The genetic material of an organism.

Involatile Substances that do not vaporize in air.

Lipocalin Family of proteins that are soluble in water that bind and transport small hydrophobic molecules.

Lordosis Female sexual behavior that enables male mounting and intromission, often involving a characteristic arched back posture.

Major histocompatibility complex A family of cell surface proteins, in vertebrates, which are required for the immune system to recognize host cells and prevent them being rejected by the acquired immune system.

Odorant A single molecule that has an odor.

Primer pheromone A pheromone that causes a change in hormonal or developmental state.

Pseudogene A gene that has lost at least some functionality due to the accumulation of mutations.

Releaser pheromone A pheromone that induces an immediate behavioral response.

Signature mixture A mixture of chemosignals that provides information about an individual.

Sympathetic Part of the nervous system that is activated during arousal.

Unconditioned stimulus In classical conditioning this refers to a stimulus that is effective in initiating a response and when paired with another stimulus will cause that stimulus to become effective in eliciting the response.

Introduction

The term pheromones was first defined over 50 years ago by Karlson and Luscher as “substances secreted to the outside of an individual and received by a second individual of the same species in which they release a specific reaction, for example, a definite behavior or developmental process” (Karlson and Luscher, 1959). This original definition is not without its limitations, and there have been several attempts to refine the original definition, although none has received widespread acceptance. The result is that although the term pheromone is in widespread use, and everyone thinks that they know what it means, different users often imbue the term with subtly different meanings. For the concept to have much use it has to describe substances that elicit innate responses that do not require learning, to distinguish them from general odorants, which come to acquire meaning and elicit specific responses only following learning (Wyatt, 2010). It has also been argued that pheromones should refer to chemical signals that evolved to have a specific signaling role, rather than simply being metabolic by-products, excretions or secretions that are sensed by general sensory mechanisms. One thing that everyone can agree on is that pheromones refer to chemical signals conveyed between individuals of the same species, but this does not necessarily mean that those signals need to be exclusive to only one species. Perhaps the weakest part of the original definition is its reference to a specific reaction, as this is open to individual interpretation regarding what constitutes a definite behavioral or developmental response. Pheromonal responses are often more variable and context dependent in vertebrates, than invertebrates, and especially so in mammals. This has led to some debate about whether the term can be usefully applied to mammals and whether mammalian pheromones actually exist (Doty, 2003). Such skepticism has been very useful in highlighting problems with the original definition and weaknesses in the quality of much of the evidence for mammalian pheromones. However, recent application of molecular genetics techniques in mice, has led to the identification and the ability to experimentally manipulate both the pheromones and their sensory receptors, resulting in an ever-increasing list of examples of mammalian chemical signals that meet the original definition of a pheromone.

The Chemical Nature of Mammalian Pheromones

Pheromones have diverse chemical structures that reflect both their metabolic origin and the information that they convey (Fig. 1). For instance, sexual attractant pheromones and alarm pheromones need to act at a distance and therefore need to be small, volatile molecules that are carried by air (there are no known examples of mammalian pheromones being carried over distance by water). A good example of such pheromones are the boar sexual attractant pheromones 5 α -androst-16-en-3-ol and 5 α -androst-16-en-3-one.

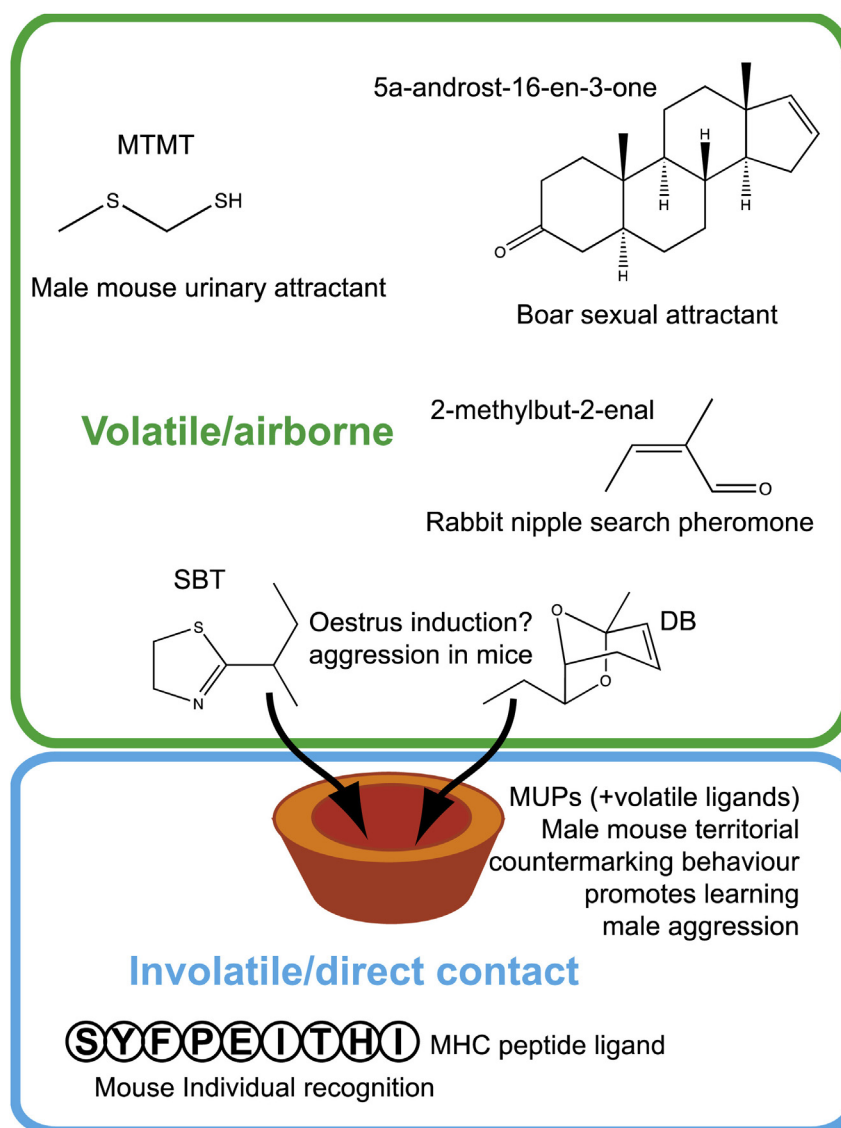

Fig. 1 Mammalian pheromones come in a wide variety of chemical structures related to their biological role of acting at a distance for volatile molecules or following direct physical contact for involatile peptides and proteins. Methylthiomethanethiol (MTMT) is found in male mouse urine and attracts females. 2-Methylbut-2-enal is found in rabbit milk and elicits nipple search behavior in neonates. 5 α -Androst-16-en-3-one is found in boar saliva and attracts and elicits mating behavior in sows. (S)-2-sec-butyl-4,5-dihydrothiazole (SBT) and (R, R)-3,4-dehydro-*exo*-brevicomin (DB) are found in male urine and induce estrus in female mice and aggression in other males. Major urinary proteins (MUPs) are found in male mouse urine and bind volatile ligands such as SBT and DB. They have numerous effects to convey individuality of males, elicit countermarking in males, elicit aggression in males, attract females and act as an unconditioned stimulus to induce learning in females. MHC peptides are found in mouse urine and convey information about individual identity.

These are derivatives of male androgen hormones with molecular masses around 272 g and are readily dispersed into the air from saliva. Another example is the mouse alarm pheromone 2-sec-butyl-4,5-dihydrothiazole (SBT), which has a molecular mass of 143 g. Both molecular mass and chemical structure affect the volatility of molecules, but in general molecules with molecular masses above about 400 g such as proteins and peptides would be expected to be relatively involatile.

Involatile substances can also function as pheromones and are ideally suited to situations where the pheromone has to be linked with a particular individual, such as the hamster vaginal protein aphrodisin, or place, such as mouse major urinary proteins (MUPs) that are used in territorial marking. Mouse MUPs are 19 kDa members of the lipocalin family of ligand binding proteins. As they are proteins, their structure is genetically determined and their relative stability across the lifespan of an individual make them ideal for conveying information about genetic identity (Sheehan *et al.*, 2016). Wild-derived mice produce around 5 of the 20 MUP variants and the profile of these variants is specific to the individual mouse that produced it. The MUP proteins themselves remain in the location in which they were deposited, which makes them ideal for a territorial marking function. Additionally, as they are also ligand binding proteins, MUPs act as a reservoir to slowly release volatile urinary ligands over a prolonged period. This not only

attracts investigation of other individuals towards the involatile MUPs, but the abundance of the volatiles being released also provides information regarding the freshness of the urine mark.

Sensory Systems for the Detection of Pheromones

The distinction between volatile and involatile pheromones has implications for the sensory systems that detect them (Fig. 2). The majority of mammalian species possess two main olfactory systems, the main olfactory system and the vomeronasal system. Species that do not possess a functional vomeronasal organ (VNO) include old-world primates including humans, fully aquatic mammals, such as cetaceans and manatees, and some species of bats. In the past, it was commonly believed that the main olfactory system detected general odorants and the vomeronasal system detected pheromones. However, this simple dichotomy has been revised in the light of more recent research and it is now accepted that in addition to its odor sensing role, the main olfactory system can also mediate certain pheromonal responses. Conversely, although many pheromonal responses are mediated via the vomeronasal system, it can also mediate non-pheromonal innate responses, such as avoidance and freezing responses to predator chemosignals. The distinguishing feature of the two systems is really in how the stimuli access the receptors. The main olfactory system is adapted to sense airborne stimuli, at a distance from the source, whereas the vomeronasal system is adapted to sense both volatile and involatile stimuli that are in the liquid phase, such as vaginal secretions, scent gland secretions or saliva, which require direct physical contact with the source. Moreover, the functions of the two systems are not as independent as originally thought. Substances acting as pheromones via the VNO are also able to stimulate sensory neurons in the main olfactory epithelium. There is also considerable convergence and integration of information from the two systems at central neural levels, such as the medial amygdala. Finally, sensory input via the main olfactory epithelium may be important to drive the direct investigation that is required for stimuli to gain access to the VNO.

The Main Olfactory System

There are a growing number examples of mammalian pheromonal responses that are mediated via the main olfactory system. For example, the sexual attractant effect of the boar mating pheromones androstenol and androstenone is not affected by blocking stimulus access to the VNO. This suggests that they are most likely to be mediated via the main olfactory system, which is also consistent with the airborne nature of the pheromones. Another example is the rabbit mammary pheromone 2-methyl-but-2-enal that elicits nipple search behavior in rabbit pups, which is vital in enabling them to suckle. Ablation of the main olfactory epithelium, but not the VNO, abolished both the nipple search behavior and general olfactory sensitivity. In mice, the ventrolateral region of the mouse MOB has even been termed the social fovea, as it predominantly responds to conspecific urinary chemosignals, such as the male urinary constituent (methylthio)methanethiol (MTMT) (Lin *et al.*, 2005). MTMT increases the attractiveness of male urine to female mice, but is inactive if presented in water. Thus, the attractant effect of MTMT depended on the context in which it was presented, which is often a feature of mammalian pheromones.

Fig. 2 Chemosensory systems for detecting pheromones in mice. Separate sensory organs, such as the Gruneberg ganglion and vomeronasal organ, detect pheromones in addition to the main olfactory system. Within the main olfactory system, separate subsystems detect pheromones and project to specific regions of the main olfactory bulb. Three main families of receptors detect pheromones in the vomeronasal organ and project to separate regions of the accessory olfactory bulb. FPRs, formyl peptide receptors; MTMT, (methylthio)methanethiol; TAARs, trace amine associated receptors.

General odors are identified by olfactory cortical regions that recognize the pattern of activity across olfactory sensory neurons that express a range of different olfactory receptor (OR) types. However, there are also olfactory subsystems within the main olfactory system, which project directly to neural systems that drive innate responses (Fig. 2). For example, neurons in the mouse MOB that receive input from OSNs expressing OR37 receptors, project directly to the medial amygdala and the paraventricular nucleus of the hypothalamus. OR37 stimuli, such as hexadecanal that is found in mouse feces, are therefore able to directly inhibit hypothalamic neurons regulating the endocrine stress response (Klein *et al.*, 2015).

A further olfactory subsystem has been identified as the subpopulation of OSNs that express members of the trace amine associated receptor (TAAR) family, which are evolutionarily unrelated to the classical family of olfactory receptors. Although some TAARs respond to non-pheromonal stimuli, such as the predator chemosignal phenylethylamine, TAAR5 has been shown to respond to trimethylamine, which is a male mouse urinary pheromone that is attractive to females (Ferrero *et al.*, 2013).

The Vomeronasal System

The VNO is both anatomically and functionally distinct from the main olfactory epithelium. It is a blind-ended tubular structure located in the nasal septum and connected to nasal cavity, and in some species also the oral cavity, by narrow ducts. The narrow lumen of the ducts means that stimulus access is limited to substances carried in mucus, which is pumped into the VNO by an active pumping mechanism. This enables the VNO to sense involatile substances that would not be conveyed in the airstream such as peptides and proteins. But the VNO is also capable of responding to smaller volatile substances that are soluble in mucus, such as SBT, which is transported in mouse urine bound to MUPs. Stimuli can be picked up from sources such as urine marks, scent marks, vaginal secretions or tear secretions, by direct nasal contact and licking of the nose, or directly from the oral cavity in species that possess a nasopalatine duct. There are two main mechanisms by which stimuli can be pumped into the VNO. In rodents, sympathetic nerve activity, in response to arousal and novelty, controls blood flow to a large blood vessel that runs along the medial side of the lumen. As the VNO is enclosed in a cartilaginous capsule, changes in blood flow in this vessel change the volume of the VNO lumen, pumping mucus carrying the vomeronasal stimuli into the organ. Carnivores and ungulates have an alternative mechanism linked to a characteristic behavior known as flehmen (Fig. 3). This behavior involved a baring of the teeth and a curling of the upper lip, which result in pressure changes that are thought to pump the stimulus-containing mucus into the VNO.

Like the main olfactory system, the vomeronasal system detects stimuli by means of G-protein coupled receptors on the surface of vomeronasal sensory neurons (VSNs). Three main classes of vomeronasal receptors have been identified, each of which only

Fig. 3 Flehmen behavior in a stallion. Note the curled upper lip and the barring of the teeth that sucks involatile stimuli into the vomeronasal organ following direct contact with the stimulus source.

distantly related to each other and to the main olfactory and TAAR receptor families. The Vmn1r class and the formyl peptide receptors (FPRs) are expressed by VSNs that are located apically in the vomeronasal epithelium. These are spatially segregated from the Vmn2r class that are both located in the basal region of the epithelium.

Vmn1rs Respond to Small Volatile Molecules

The analysis of a wide range of mammalian genomes has revealed dramatic variations in number of Vmn1rs (Young *et al.*, 2010). Around 240 intact Vmn1r genes have been identified in the mouse genome. Other species with a large number of functional Vmn1rs include the platypus, mouse lemur and rabbit, each with over 160 receptors. Other lagomorphs and rodents have around 60–110 functional Vmn1r genes, but most domestic species and companion animal species have far fewer: 40 in cows; 36 in horses; 28 in cats; and 9 in dogs. Numbers of functional Vmn1rs are low in old world monkeys and apes: 3 in baboons, gorillas and humans; 4 in chimpanzees; 5 in orangutans. Certain species appear to have no functional Vmn1rs at all including, little brown bats, macaques and cetaceans such as dolphins. In mice, Vmn1rs detect small volatile molecules, which have been shown to have pheromonal activity in mice, such as SBT, 3,4-dehydro-exo-brevicomin (DB), farnesenes and 2-heptanone (Leinders-Zufall *et al.*, 2000). These responses were found to be highly selective and also highly sensitive, with cells responding at concentrations as low as 10^{-11} M. This high level of sensitivity is a common feature of pheromone detecting systems that need to detect small amounts of signal that have been released into the environment. In addition to detecting these urinary volatiles, Vmn1rs have also been found to respond to sulphated steroids. Imaging of VSN responses in slices of VNO epithelium have revealed groups of receptors that specifically respond to derivatives of oestrogens, progestogens, androgens and corticosterone, suggesting the potential for detection of hormonal state of the producer (Isogai *et al.*, 2011), although the biological significance of this is currently unknown.

Vmn2rs Respond to Peptides and Proteins

Genomic analysis has identified around 120 intact Vmn2r genes in the mouse genome (Young and Trask, 2007). As is the case for Vmn1rs the Vmn2r repertoire varies dramatically across species, with rats and opossums possessing around 80–90 functional Vmn2rs. In contrast, several other mammalian species including cows, dogs, macaques, chimpanzees and humans appear to have no functional Vmn2rs, with only non-functional pseudogenes remaining in the genome (Young and Trask, 2007). In mice, Vmn2rs have been found to respond to involatile peptides and proteins, such as exocrine secretory protein 1 (ESP1). ESP1 is a 7 kDa peptide, that is produced by the tear glands of male mice. It selectively activates VSNs expressing the Vmn2r116 (V2Rp5) receptor (Haga *et al.*, 2010). Moreover, female mice, in which this receptor has been genetically deleted, show a reduced rate of female sexual behavior, known as lordosis, confirming the role of ESP1 as a sexually-dimorphic sex pheromone in mice. Other peptides that can be sensed by mice Vmn2rs include major histocompatibility complex (MHC) peptide ligands. These 9-amino acid peptides play a role in self/non-self recognition by the immune system, suggesting that they can also convey information about the genetic identity of the producer (Leinders-Zufall *et al.*, 2004). Vmn2rs are even more sensitive than Vmn1rs, with VSNs expressing Vmn2r26 (V2R1b) responding MHC peptides at a concentration of 10^{-14} M. This makes them one of the most sensitive chemical detection systems known.

Other Vmn2r stimuli include MUPs, which are members of the lipocalin family of ligand binding proteins. MUPs bind small volatile ligands, several of which are known pheromones that stimulate Vmn1rs. However, even when these volatiles have been displaced, MUPs still elicit aggression from male mice and lactating female mice when painted onto a normally unthreatening castrated male. This suggests that the MUPs can function as involatile pheromonal stimuli in their own right, via activation of Vmn2rs, in addition to carrying volatile pheromonal stimuli that act at Vmn1rs.

FPRs Respond to Infection-Related Peptides

The mouse genome contains seven functional FPRs of which five are expressed in the VNO. FPRs expressed in VSNs appear to respond to formylated bacterial peptides, such as lipopolysaccharide (LPS). They potentially have a similar role to FPRs in the immune system in detecting bacterial contamination and inflammatory responses. Evidence for this suggestion has come from mice that have been injected with LPS, or infected with natural pathogens. Other mice avoid both the diseased mice and their urine, and this avoidance behavior was not observed in mice with deficient vomeronasal function, strongly suggesting this pheromonal effect is mediated by vomeronasal FPRs (Boillat *et al.*, 2015).

Releaser Pheromonal Effects on Behavior

Releaser pheromones have immediate effects on the behavior of the receiver (Table 1). For example, the boar sexual attractant pheromones 5 α -androst-16-en-3-ol and 5 α -androst-16-en-3-one are accumulated in the boar's saliva by association with pheromone binding proteins. In the presence of a receptive sow, the boar salivates copiously, releasing the pheromones into the air. They cause the female to be attracted to the male and elicit female sexual behavior, known as standing, that enables the male to mate. A similar behavioral effect is elicited by the sex pheromone ESP1 in mice. The detection of this peptide in tear secretions, during investigation of males, more than doubles the rate of lordosis behavior of females (Haga *et al.*, 2010). Interestingly, males of the C57BL/6 inbred mouse strain naturally lack ESP1 production. This demonstrates that pheromonal deficiencies in certain

Table 1 Examples of mammalian pheromones, their nature, detection mechanism and effects

Pheromone	Nature	Species	Producer	Source	Receiver	Sensory system	Effects
2-Methylbut-2-enal	Volatile	Rabbit	Lactating female	Skin Milk	Neonates	MOS	Arousal Nipple search Learning
5 α -androst-16-en-3-one	Volatile	Pig	Adult male	Saliva	Female	MOS	Attraction Lordosis
(Methylthio)mentanethiol	Volatile	Mouse	Adult male	Urine	Female	MOS	Attraction
SBT+DB	Volatile	Mouse	Adult male	Urine	Female Male	VNS (Vmn1r)	Estrus induction Aggression
Sulphated steroids	Involatile	Mouse	Male and female	Urine	Male and female	VNS (Vmn1r)	Information on endocrine state
Formyl peptides	Involatile	Mouse	Male and female	Urine	Male and female	VNS (Vmn1r)	Information on infection state
ESP1	Involatile	Mouse	Adult male	Tears	Female	VNS (Vmn2r)	Lordosis
ESP22	Involatile	Mouse	Juvenile	Tears	Male	VNS (Vmn2r)	Inhibits sex behavior
MUP20 (darcin)	Involatile	Mouse	Adult male	Urine	Female Male	VNS (Vmn2r)	Attraction Learning Countermarking Aggression
Other MUPs	Involatile	Mouse	Adult male	Urine	Male and Female	VNS (Vmn2r)	Individual recognition
MHC peptide ligands	Involatile	Mouse	Adult male	Urine	Female	VNS (Vmn2r)	Individual recognition
Aphrodisin	Involatile	Hamster	Adult female	Vaginal secretions	Male	VNS (Vmn2r?)	Stimulates sex behavior

Abbreviations: DB, (R, R)-3,4-dehydro-exo-brevicomine; ESP, exocrine secretory peptide; MOS, main olfactory system; MHC, major histocompatibility complex; MUP, major urinary protein; SBT, (S)-2-sec-butyl-4,5-dihydrothiazole; VNS, vomeronasal system.

strains of mice, due to inbreeding, may not only affect their reproductive success, but also their usefulness in studies of natural reproductive behavior.

Another member of the ESP family of peptides, ESP22 is also produced by the tear glands but this time of juvenile mice of both sexes. Notably juveniles of the CBA and CH3 inbred strains lack ESP22 production and are subject to a high rate of inappropriate sexual behavior from adult males. However, if ESP22 is painted onto these juveniles then it reduces the level of male sexual behavior towards them to a low level typical of the other inbred strains that naturally produce the peptide (Ferreiro *et al.*, 2013). Therefore, ESP22 is acting as a releaser pheromone, via the vomeronasal system, to inhibit male sexual behavior. Such inhibitory releaser effects of pheromones can only be observed in the contexts of other behaviors and it is therefore not surprising that they have only recently been identified.

Yet another class of releaser sex pheromone is produced by female hamsters in their vaginal secretions. This pheromone is aphrodisin, a 17 kDa member of the lipocalin family of ligand binding proteins. When the protein containing fraction of vaginal fluid was painted onto an anaesthetized male hamster, it elicited mounting behavior in other males (Briand *et al.*, 2004). This effect is mediated by the vomeronasal system, but the vomeronasal system is only necessary to stimulate sexual behavior in sexually naïve males. Subsequent male sexual behavior can be elicited by female odor cues, sensed by the main olfactory system, which were learned during the first sexual experience. As these odor cues are eliciting a learned response, they would not be regarded as pheromones even though they elicit the same behavioral response as aphrodisin. Presumably this is an evolutionary adaptation to reinforce the appropriate behavioral response being elicited in a certain context.

Indeed, pheromones themselves can act as unconditioned stimuli to induce the learning of other chemosignals. One example of this is the rabbit mammary pheromone 2-methylbut-2-enal, which is produced by the skin around a lactating doe's nipples and is present in their milk. This pheromone is vital to the reproductive success of rabbits, as it elicits the stereotyped nipple search behavioral response in the neonates, enabling them to locate the nipples and suckle. However, when neonates were exposed to 2-methylbut-2-enal paired with an artificial odor, without suckling, the artificial odor alone was subsequently effective in eliciting nipple search behavior (Coureaud *et al.*, 2006). Another example of learning is the atypical male mouse MUP20, also known as darcin. This has a releaser pheromonal effect to attract female mice to urine marks. But it also acts as an unconditioned stimulus to induce the learning of the volatile odor signatures associated with the urine mark, as well as the context in which the urine mark occurs. These examples show that pheromonal stimuli can have dual roles of releaser pheromone and unconditioned stimulus and can be mediated by both the main olfactory and vomeronasal systems (Fig. 4). But when MUP 20 is sensed in the context of another individual, such as being painted on a castrated male, it has a different releaser pheromonal effect to elicit male aggression. This demonstrates the potential for pheromones to have multiple functions and that it is more useful to specify the pheromonal effects of a chemosignal rather than just identifying it as a pheromone. A further complexity is revealed by the ability of female mice to respond to MUP20 being dependent on their hormonal state. Increased progesterone during the non-receptive phase of their estrus cycle selectively silences activity of the VSNs that respond to MUP 20 without affecting other VSNs that respond to

Fig. 4 Pheromones can be sensed by both the main olfactory system and the vomeronasal system, which converge in central brain areas such as the amygdala. Coordinated behavioral and physiological responses are driven by brain areas such as the hypothalamus. Identifying mammalian pheromones is complicated by learning, by which non-pheromonal odors sensed by the main olfactory system can drive pheromonal-like responses. A further complication is the context dependence of pheromonal responses, which may be influenced by other sensory cues as well as hormonal state.

predator chemosignals (Dey *et al.*, 2015). Once again this shows the context dependence of mammalian pheromonal effects that can lead to variability in the responses observed.

Primer Pheromonal Effects on Endocrine Responses

Primer pheromonal effects are longer-term effects on endocrine or developmental state (Table 1). For example, the Vandenberg effect is the acceleration of puberty in pre-pubertal female mice that are exposed to urine from adult males. This effect is mediated by stimulation of gonadotropin hormone releasing hormone neurons in the hypothalamus. It therefore has a similar neuroendocrine basis to the Whitten effect, which is the effect of adult male urine to induce and synchronize estrus in female mice. Conversely, exposure to female urine has the opposite effect of delaying puberty and lengthening estrus. Given their similar nature, the Vandenberg and Whitten effects have been proposed to be mediated by the same urinary pheromones. Previous reports had implicated androgen dependent urinary volatiles such as SBT, DB, 6-hydroxy-6-methyl-3-heptanone, α - and β -farnesene (Novotny *et al.*, 1999), which are bound by MUPs, and stimulate Vmn1rs (Leinders-Zufall *et al.*, 2000). But the effectiveness of these urinary volatiles has been disputed and the identity of these mouse primer pheromones underlying these pheromonal effects is unclear. A similar primer pheromonal effect, known as “male effect”, also occurs in sheep and goats. In these species, exposure of females to androgen-dependent pheromonal stimuli associated with head hair of males is sufficient to induce estrus in seasonally-anestrus females. Detailed analysis of the volatile compounds extracted from goat hair led to the identification of a single molecule, 4-ethyloctanal, which induces activity in the GnRH pulse generator (Murata *et al.*, 2014). However, 4-ethyloctanal has not yet been shown to be effective in inducing estrus in goats and it is likely that other components also contribute to the response.

Signature Mixtures Convey Information About Individuals

The pregnancy block effect, or Bruce effect, as it is known, is another primer pheromonal effect in mice. Exposure of a recently mated female mouse to male urine, during the first few days following mating, results in a reduction in progesterone levels, leading to implantation failure and return to estrus. However, pregnancy block does not occur in response to urine from the male that has mated with the female. This is because the female learns the chemosensory signature of their mate during a sensitive period following mating, which subsequently inhibits activation of the neuroendocrine pathway resulting in pregnancy block. The individuality of the mate’s chemosensory signals appears to be conveyed by MHC peptide ligands, as adding MHC peptide ligands typical of an unfamiliar strain to the mating male’s urine causes it to block the pregnancy of his mate (Leinders-Zufall *et al.*, 2004). These individuality signals would not classically be classed as pheromones, as their effects depend on learning. Instead they have been referred to as either signaler pheromones, or more recently as signature mixtures that provide information about individuals without directly eliciting a pheromonal effect (Wyatt, 2010).

Human Pheromones

As yet no pheromonal stimuli have been convincingly identified in humans in the same way that they have in other mammalian species. One reason for this might be the difficulty in looking for a definite behavioral response when much of human behavior is influenced by learning and societal expectations, which are difficult to control experimentally. But humans are a smelly species and become smellier after puberty. Therefore, it is likely that pheromones have existed in the recent evolutionary past. But whether they are still functional in modern society, or whether they have become non-functional, as have some pheromonal signals in different inbred mouse strains, remains to be determined. Past studies tend to have focused on effects on sexual preferences and indirect measures of sexual behavior. However, pheromonal effects may occur during more intimate sexual investigation, which is

particularly difficult to study in humans. More progress is likely to be made by in identifying possible pheromones involved in suckling behavior and possibly maternal bonding where contextual factors are more constant (Wyatt, 2015).

Conclusions

The recent application of molecular genetics techniques has revolutionized our understanding of the role of pheromones in mammalian behavior. And yet there are still many more receptors that have been identified than the pheromones that stimulate them and the effects that they mediate. Most of the recent advances in our understanding of mammalian pheromonal communication is based on studies of mice. But by their very nature, pheromonal signals have evolved species-specific roles, and a major challenge is to translate our understanding of pheromones in mice to the study of other species, in which genetic manipulation is not currently possible. What is becoming increasingly clear is the important role played by pheromonal signals in the reproductive biology of most mammals.

Olfaction and Reproduction: Olfactory Imprinting and Homing in Salmon

Introduction

For many fish species, non-visual sensory systems play a critical role in survival and reproduction. In the aquatic environment, visual cues can be easily perturbed due to low light levels and increased turbidity, making recognition of distant objects nearly impossible. However, non-visual cues, such as auditory and odorant cues can travel long distances, and convey important information about a fish's surroundings independent of vision; making these sensory systems important in the aquatic environment. The olfactory system, in particular, plays a central role in many aspects of a fishes life cycle. Odorants in the water column can inform a fish of nearby food, predators, reproductive status of potential mates, conspecifics (same species), as well as favorable habitats for spawning and rearing (Hara, 1992).

For salmon, in particular, olfaction plays a critical role in all aspects of its life cycle. The life cycle of salmon plays out over large temporal and geographical scales, and in many different and dynamic environments. All salmon spawn in fresh water, and most salmon species have an *anadromous* life history, meaning they spend a portion of their life cycle in saltwater environments. The anadromous life history that salmon utilize affords them an enormous amount of rapid growth potential as well as the ability to support a disproportionately large population size produced from a relatively small freshwater systems due to the incredible abundance of food and space in the ocean environment. The anadromous life history does come at an expense however by increasing the risk of mortality as well as a greater demand on the ability to navigate over long distances, and achieve reproductive success. The latter is especially important as many salmon have a *semelparous* reproductive cycle, meaning that once they spawn they die soon after. The salmon olfactory system not only makes the anadromous life cycle possible, but also greatly increases the odds of survival and reproductive success.

A Brief Outline of the Salmon Life Cycle

Salmon start out life as an embryo residing in the interstitial spaces of a gravel mound known as a *redd*. A redd is the nest that the female salmon builds while depositing her eggs during mating. The embryos often incubate within the redd for up to several months before the tiny salmon hatch. At hatching, the juvenile salmon is known as an *alevin*, which survive off a large external yolk sac of nutrients. After their yolk sacs are depleted, the alevin migrate up and out of the gravel and emerge as *fry*. Fry must now feed on their own, and depending on the species, either migrate to the ocean immediately or stay and rear in the freshwater environment (Fig. 1).

Depending on the species, after rearing in the freshwater environment (for days to years), the juvenile salmon migrate to the ocean. During this migration downstream and upon entering estuaries, juvenile salmon undergo many physiological changes to

Fig. 1 Salmon lifecycle.

prepare them for survival in the marine environment. Their coloration changes from dark green to silver, their shape and behaviors change and many aspects of their physiology change including energy storage and osmoregulatory processes. During this transitional period between the fresh and saltwater environments, the juvenile salmon are known as *smolts*. Smolts will generally spend between days and months in the estuarine environment before making the final transition to the open ocean migration. Ocean phase salmon spend between 1 and 5 years at sea, depending on the species, before reaching sexual maturity and migrating back to freshwater to spawn in the natal stream they came from.

The Salmon Olfactory System

Morphology of the Olfactory Sensory System

The salmon olfactory system is a tightly coordinated and complex signaling system made up of several distinct neural centers (Fig. 2). The peripheral component of the olfactory system in salmon is composed of a pair of rosette shaped structures. Each rosette is located in a small pit on either side of the salmon's head. The olfactory pits have two openings that aid in directing water into and out of the pit to increase the water-sampling rate as the salmon swims through the water. The rosettes are made up of lamellae each covered in both non-sensory and sensory olfactory epithelia. The olfactory sensory epithelia is arranged in a pseudostratified layer comprised of several major olfactory cell types of both sensory and non-sensory function (Fig. 2). The cell types include sustentacular cells (SUS cells), which provide both structural support and a glial like role in supporting the mature olfactory sensory neurons (OSNs); goblet cells, that produce a protective mucosal layer; crypt cells, which are thought to detect odorant molecules; mature ciliated and microvillar OSNs, which detect odorant molecules; immature OSNs, their role is to replace the injured or senescing mature OSNs; and two classes of multipotent olfactory stem cell (OSC) populations, the globose basal cells (GBCs) and horizontal basal cells (HBCs), which can potentially generate and replace all of the cells that make up the olfactory sensory epithelium during natural cellular turnover, or following an injury (Døving, 2007). All of these cell populations work in coordination to form a functional peripheral olfactory system. As previously mentioned, it is the role of the ciliated and microvillar OSNs and crypt cells to detect odorants and send that signal to the central olfactory system in the brain. Initially, when an odorant binds to an odorant receptor (a G-protein coupled receptor, GPCR), located on the surface of cilia or microvilli of an OSN. This odorant binding initiates a cascade of signaling molecules, which ultimately open calcium and chloride ion channels that send a signal down the olfactory axonal bundle to the olfactory bulbs where the signal is decoded and a behavioral response is decided (DeMaria and Ngai, 2010; Whitlock, 2006).

Types of Odorant Receptors

The salmon olfactory system, and all vertebrates, are thought to employ the "one receptor-one neuron" rule, which means that each OSN only expresses one type of odorant receptor (Lewcock and Reed, 2004; Sato *et al.*, 2007; Serizawa *et al.*, 2003). Furthermore, the

Fig. 2 Morphology of olfactory system.

salmon olfactory system utilizes between 100 and 200 unique putative odorant receptors (Johnstone *et al.*, 2012). The odorant receptors are divided into four main classes: the main olfactory receptors (mORs) and the trace-amine associated receptors (TAARs), which are located in ciliated OSNs and the vomeronasal type 2 receptor-like (Olfc) and vomeronasal type 1 receptor-like (ora), located in the microvillar OSNs. It is important to note that while salmon have odorant receptors that are characterized as vomeronasal receptors, they do not in fact have a distinct and separate vomeronasal sensory region like many other vertebrates. In fish, OSNs of all classes are arranged in a mosaic with no clear boundaries based on functional class between them. Functional characterization, i.e. odorant specificity, of the currently identified putative salmon odorant receptors within each of the major classes has not been completed; however, research in zebrafish and other vertebrate species has provided some insight into their possible specificities (Behrens *et al.*, 2014; Jiang *et al.*, 2015). For example, it is widely accepted that vomeronasal odorant receptors, associated with microvillous OSNs, play a large role in the detection of pheromone odorants and amino acids. Odorant receptors associated with ciliated OSNs likely also detect amino acids and other odorant cues not related to pheromones such as nucleotides released from food sources (Hansen *et al.*, 2003; Sato and Suzuki, 2001). In addition to the different classes of odorant receptors detecting different types of odorants, each major OSN class, i.e. ciliated and microvillous OSNs, further utilize distinct signaling machinery to relay specific odorant signals to the brain. The ciliated OSNs utilize a cAMP/adenylyl-cyclase III (ACIII) mediated pathway, whereas microvillar OSNs utilize an inositol triphosphate (IP3)/Phospholipase-C (PLC) mediated pathway. Each pathway utilizes calcium, chloride and sodium channels for signaling to propagate an odorant-induced signal to the olfactory bulb.

The salmon olfactory system may have up to 200 putative odorant receptors and is tasked with detecting many unique water-borne odorants (Johnstone *et al.*, 2012). To identify specific odorants, the brain uses a combinatorial signal integration method for odorant identification, wherein an single odorant may activate several different odorant receptors at the same time (Malnic *et al.*, 1999). Having one odorant activate a set of unique odorant receptors provides each odorant a unique identifier, a “fingerprint” that the brain can identify. This combinatorial activation method can potentially produce billions of unique odorant “fingerprints”, thus allowing the olfactory system to detect far more odorants than it has unique odorant receptors. The correct identification of odorants is important in allowing salmon to complete their life cycle, such as when adult salmon home back to their natal stream using olfactory cues associated with their home stream. Salmon learn these odor mixtures as juveniles prior to their seaward migrations through a process known as *imprinting*.

Salmon Life History and the Role of Olfaction

Downstream Migration and Imprinting

From the moment salmon emerge from the gravel, olfaction plays a critical role in their survival. Juvenile salmon use their sense of smell to locate food, detect predators and nearby kin. One critical function of the juvenile salmon olfactory system is imprinting on the odorant signature of their natal waters. It has been known for some time that adult salmon have an amazing ability to find their way back to their natal waters after being away for years. However, it was not until experiments by Arthur Hasler and his colleagues (Cooper *et al.*, 1976; Hasler and Scholz, 1983; Scholz *et al.*, 1976) that the link between the chemical make up of their rearing waters and their sense of smell were definitively tied to their successful homing abilities. In a classic series of experiments, they exposed groups of salmon from a hatchery to the natural water source at the hatchery or hatchery water plus artificial odorants, the chemical phenethyl alcohol (PEA) or morpholine (compounds that do not naturally occur in their rearing water). Following exposure to these different water chemistries, the fish were marked and transported and released into an unfamiliar lake. When these fish matured and began their spawning migrations, the researchers pumped the artificial odorants into unfamiliar streams and monitored the lake tributaries for returning salmon. Upon their return migration, over 90% of the salmon exposed to the artificial odorants were recovered in the stream scented with their exposure odorant while the control fish were scattered in tributaries throughout the lake. This landmark research showed that olfaction not only played a critical role in a salmonid’s ability to navigate back to their natal waters for spawning, but also that as juveniles they did indeed imprint on the scent of their rearing waters.

The parr-smolt transition (PST) is thought to be a particularly important period for olfactory imprinting in juvenile salmon (Dittman and Quinn, 1996). However, some salmon species, such as pink, chum and sockeye salmon, migrate away from their natal site very soon after emergence from the gravel. These salmon species would therefore not have much time to imprint on the scent of their natal waters after they emerge compared to other salmon species, which spend weeks to months in their natal waters. However, these species still possess the ability to home back to their natal waters with relatively high accuracy, indicating that odor imprinting must occur in earlier life-stages as well. Indeed, research has shown that to overcome this shortened residency time upon emergence, both pink and sockeye salmon have the ability to imprint on the scent of their natal waters during the alevin stage while they are still buried in the gravel of the redds (Tilson *et al.*, 1994; Bett *et al.*, 2016; Havey *et al.*, 2017).

During these windows of odorant imprinting, there is strong evidence that the release of hormones at these key moments may play a major role driving odorant imprinting (Nevitt and Dittman, 1998). It has been determined that when juvenile salmon experience novel stimuli, such as new water chemistries and environments, during rearing and during their downstream migration, they concomitantly experience surges in thyroxine (T4), later converted to triiodothyronine (T3) within the olfactory system (Lema and Nevitt, 2004). As previously mentioned, the PST represents a critical and sensitive time for odorant imprinting in the juvenile salmon olfactory system (Dittman and Quinn, 1996) and during the PST there is also a surge in circulating thyroxine (T4) levels within juvenile salmon. These hormonal surges are very important, as the conversion of T4 to T3 hormone within the olfactory system drives the proliferation of sensory cells that may be important in odorant imprinting (Lema and Nevitt, 2004).

A more complex and dynamic environment for young salmon aids in their ability to correctly imprint and thus navigate back for spawning. Indeed juvenile salmon imprinting on novel odorant stimuli in changing aquatic environments as they migrate downstream allows them to use these unique cues as navigational way-points later on as they migrate back upstream as adults to spawn (Quinn, 2011). Without unique cues and sequential imprinting on unique odorant mixtures, it would be extremely difficult to imagine a salmon being able to correctly navigate back to its natal waters. Returning adult salmon are unlikely to smell their natal waters at the mouth of a large river. This would be akin to trying to successfully navigate your car across the country with no road signs except for the last few miles of your journey. Using memorized waypoints allows them to overcome that hurdle and successfully migrate up the correct bodies of water.

Return Migration

When ocean-phase salmon begin to mature and are ready to make the return migration for spawning, the olfactory system again plays a central role in completing their life-cycle. The initiation of the home stream migration coincides with an elevation in gonadotropin releasing hormone (GnRH) levels in the brain (Takeshi *et al.*, 2010). In response, maturing salmon experience elevated levels of the gonadotropin follicle-stimulating hormone (FSH) which stimulates vitellogenesis and gonadal development. As salmon enter freshwater and approach their natal river, GnRH levels in other regions of the brain influence migratory behavior and olfactory function (Dittman *et al.*, unpublished; Ueda *et al.*, 2016). Finally, as salmon near their spawning grounds, GnRH induces surges in the gonadotropin luteinizing hormone (LH) that stimulate elevated plasma levels of the steroid $17\alpha,20\beta$ -dihydroxy-4-pregnen-3-one (DHP) involved in final maturation.

GnRH and maturation appear to play an important role in migratory behavior during the spawning migration. Experiments in which salmon were displaced downstream after returning to their natal site, demonstrated that the time to return to the homesite declined as salmon neared final maturation suggesting a strong motivation to return as fish neared final maturation (Dittman *et al.*, unpublished, Ueda, 2011). In subsequent experiments, displaced salmon injected with GnRH implants returned more quickly than sham controls indicating that homing behavior is affected by maturation-associated hormones (Dittman *et al.*, unpublished, Ueda, 2011). Indeed, mature but not immature salmon were attracted to imprinted odors in studies with coho salmon (Hasler and Scholz, 1983; Dittman *et al.*, 1996) but whether this reflects an inability to recognize imprinted odors or a lack of motivation to respond to them is not clear. However, it does indicate that mature and immature salmon respond differently to odors learned as juveniles. It is important to note that homing and maturation are not inextricably linked. Many populations of salmon migrate back to their river of origin months before maturing (e.g., spring chinook salmon and summer steelhead). In these races, fish may home hundreds of kilometers upriver to the general vicinity of their natal stream, then hold in the main-stem river for several months before resuming their homing migration to their spawning site (Quinn *et al.*, 2016).

In addition to the behavioral effects of maturation on migratory behavior, the olfactory system itself is affected by the maturation process. For example, it has been demonstrated that olfactory sensitivity to reproductive pheromones is enhanced as fish mature. Several experiments have demonstrated that treatment with androgens induced increased olfactory sensitivity to reproductive pheromones in several cyprinid species (Cardwell *et al.*, 1995; Belanger *et al.*, 2010; Ghosal and Sorensen, 2016). Salmon are similarly responsive to reproductive pheromones during spawning (Yambe *et al.*, 2006) but a direct link between maturation and heightened olfactory sensitivity to these pheromones has not been demonstrated. However, electrophysiology, heart rate conditioning, and cellular studies of olfactory function have indicated that olfactory sensitivity to imprinted odorants increase during maturation (Hasler and Scholz, 1983; Dittman *et al.*, 1997). Experimental GnRH treatments of immature salmon or maturing salmon nearing their natal site increased their olfactory sensitivity to imprinted waters (Hasler and Scholz, 1983; Ueda *et al.*, 2016). One aspect of the imprinting process involves sensitization of the peripheral olfactory system (sensory neuron in the sensory epithelium of the olfactory rosette) to specific imprinted odorants (Nevitt *et al.*, 1994). Dittman *et al.*, (1997) demonstrated that sensitivity of signal transduction enzymes to imprinted odors in the sensory neurons of the olfactory epithelium increased only at the time of the homing migration as fish were maturing. This heightened sensitivity to imprinted odors may also be due to changes in expression of odor receptor proteins induced by maturation. Transcriptomic analysis comparing mRNA expression in the olfactory epithelium of immature and mature eels and salmon indicated that specific odorants receptors and olfactory signaling genes are unregulated in mature fish (Churcher *et al.*, 2015; Palstra *et al.*, 2015).

Conclusion

Salmon have an extraordinary life cycle, highlighted by their dramatic reproductive homing migrations which take them from oceanic feeding grounds back to their river of origin to spawn. At every stage in these migrations, there is a complex interplay between the reproductive endocrine axis and olfaction that allows a salmon to successfully return to their natal stream to spawn.

REPRODUCTION, OVERVIEW BY PHYLOGENY

Sponge Reproduction

Alexander V Ereskovsky, Avignon University, Marseille, France; and Saint-Petersburg State University, St. Petersburg, Russia

© 2018 Elsevier Inc. All rights reserved.

Sponges (phylum Porifera) branch basally in the metazoan phylogenetic tree and comprise four distinct lineages in the rank of classes: Demospongiae, Hexactinellida, Calcarea and Homoscleromorpha. Recent Porifera number about 9000 species living in all aquatic environments at all depths. A sponge is traditionally defined as “a sedentary, filter-feeding metazoan.” They have no nerves, muscles, special digestive system or gonads. However, sponges and eumetazoans share the basic features of sexual reproduction such as oogenesis, spermatogenesis, gametes, morphogenesis etc.

The data on the reproduction must be accumulated and compared between the sponge lineages and eumetazoans in order to understand the early evolution of the animal reproduction and patterning in the relation to the genome evolution. Sponges are a key group to provide significant answers to these fundamental evolutionary questions.

Modes of Reproduction

Gonochorism and hermaphroditism as well as viviparity, oviparity, and ovoviviparity occur in sponges. The data on the sex phenotype have been obtained mainly from Demospongiae (Table 1). However, it was demonstrated that oviparous sponges are chiefly gonochoric, but viviparous (brooding) sponges chiefly are hermaphrodites.

Sequential or successive hermaphroditism (or sex reversal) is a type of the hermaphroditism that occurs when the individual changes sex at some period in its life. It can be change from a male to female (protandry), or from a female to male (protogyny). Successive hermaphroditism has been documented in only a few cases in demosponges and therefore the real extent of this phenomenon cannot be properly evaluated at the moment. This type of hermaphroditism has been indicated in: *Polymastia mammillaris*, *Suberites massa*, *Hymeniacion perlevis*, *H. heliophila*, *Chalinula ecbasis*, and *Spongilla lacustris*. A careful analysis of the sex cycle is also necessary to avoid confusion between hermaphrodite species with sexual phases far apart in time and gonochoric species.

Contemporaneous hermaphroditism is more common than successive and well known in many demosponges (order Poecilosclerida), some Homoscleromorpha and Calcarea. Some species could include mostly contemporaneous hermaphrodites in a population in co-existence with a few gonochoristic individuals and vice versa, populations consisting mainly of gonochoristic individuals have been showed to contain some contemporaneous-hermaphroditic individuals.

Both oviparity and viviparity (brooding) exist in sponges. In contrast to the sex phenotype, oviparity and viviparity are stable features of individuals and species. Viviparous sponges release larvae and the oviparous sponges release zygotes or unfertilized eggs.

Viviparity and oviparity are equally widespread reproductive modes in sponges. The embryonic development in the oviparous sponges is always external, leading to free-swimming larvae. Viviparous or ovoviviparous sponges are characterized by brooding of embryos in the mesohyl or inside the special temporary structure – follicles. Resulting free-swimming larvae release through the canals of the aquiferous system. The direct development without larval stage exists in some demosponges. In Demospongiae some orders are completely oviparous (Polymastiida, Clionaida, Tethyida, and Verongida), while other – have only viviparity (Spongillida, Dendroceratida, Dictyoceratida). However, some viviparous representatives can be found in the oviparous orders, for example, the viviparous genera *Alectona*, *Thoosa*, *Stylocordyla* (order Suberitida), genus *Halisarca* (order Chondrosida), genera *Haliclona*, *Xestospongia* (order Haplosclerida).

Viviparity in sponges often correlates with the hermaphroditism. For example, all investigated Hexactinellida, Homoscleromorpha and Calcarea are viviparous and hermaphrodites.

No sexual dimorphism exists in gonochorists or successive hermaphrodites.

Sexual Versus Asexual Reproduction

Asexual reproduction is an important reproductive strategy for sessile organisms such as sponges, and represents a significant evolutionary advantage that can compensate for the fact that mature adults are unable to move and search for mates. Sponge asexual reproduction may proceed by fragmentation, budding and gemmulogenesis.

The simplest mode of asexual reproduction is fragmentation. Fragmentation is characteristic for attached organisms with a low degree of integration and high regeneration capacities. It occurs accidentally, and the separation of the fragment from the parental sponge is not preceded by any changes in the cells composition. Fragmentation is widespread in Demospongiae and mostly occurs in the sponges whose body branches or bears projections. Fragmentation may be triggered by various factors: wave impact during storms, the activities of predators such as fishes and turtles, certain infections, ruptures and splits of the substrate and, in the case of encrusting sponges, growth of the sponge body.

Table 1 Sex phenotype, oviparity & viviparity, larval type, and asexual reproduction distribution in the phylum Porifera

<i>Taxa</i>	<i>Sex phenotype</i>	<i>Reproductive conditions</i>	<i>Larval type</i>	<i>Asexual reproduction</i>
Class Hexactinellida

Subclass Calcinea	?	V	Ca	B

Abbreviations: Sex phenotype – G, gonochorisme; H, hermaphroditisme. Reproductive conditions – O, oviparity; V, viviparity. Cleavage pattern – Ch, chaotic; Ra, radial-like; In, incurvational; Po, polyaxial. Larval type – Am, amphiblastula; Ca, calciblastula; Ci, cinctoblastula; Co, coeloblastula; D, direct development Di, disphaerula; Ho, hoplitomella; Pa, parenchymella; Tr, trichimella. Asexual reproduction – B, Budding; F, fragmentation; G, gemmulogenesis; No, absence.

A general feature of budding in all investigated sponges, except Homoscleromorpha, is migration of the polypotent and some differentiated cells from the internal parts of the parental sponge to the ectosomal region, formation of the ectosomal cell aggregate, and development of a more or less dense bud. Budding in Homoscleromorpha does not involve the migration of cells from the mesohyl and their integration into the forming bud. In Homoscleromorpha bud development is based on the epithelial morphogenesis, i.e., the forming bud is simply an outgrowth of the parental sponge's body wall.

Gemmulogenesis was described only in demosponges. Gemmules develop from the polypotent archaeocytes. It usually occurs after completion of sexual reproduction or, more rarely, during embryogenesis. Gemmulogenesis starts with directed migration of the gemmule nurturing cells, archaeocytes and spongocytes into certain parts of the mesohyl, where they form dense aggregates. Archaeocytes in these aggregates actively phagocyte nurturing cells and symbiotic zoochlorellae. Gemmule envelope formation starts at one of the poles and gradually spreads to the other one, where a micropyle, a spicule-free area, is later formed. A fully-formed gemmule consists of a dense non-cellular envelope and the homogenous internal mass of thesocytes, originated from archaeocytes. The latter have numerous yolk plates or yolk granules. Gemmulogenesis is accompanied by a considerable or complete disorganization of the aquiferous system and the mesohyl of the parental sponge.

Asexual reproduction can occur occasionally. For instance, occasional budding is found in almost all sponge clades and in any type of habitat, but it is observed regularly among marine representatives of Porifera. Some cases of obligatory asexual reproduction have been recorded in many demosponges (orders Spongillida, Tethyida, Clionaida, Suberitida, Polymastiida and Tetractinellida). For instance, gemmulogenesis occurs in all families of Spongillida, except Lubomirskiidae, in the families Clionaidae (Clionaida) and Suberitidae (Suberitida). Obligatory budding has been recorded in the families Polymastiidae and Tethyidae.

When asexual reproduction exists in Demospongiae, the life cycle often presents a regular alternation of sexual and asexual phases. Potential explanations for this alternation rely on the "competition" for cells, especially for archaeocytes, which are likely polypotent cells, between these two reproduction modes.

Under unfavorable environmental conditions, some sponges become dormant and may remain in a dormant state for long periods. Such dormancy is often associated with the asexual reproduction.

Reproductive Strategies: Exogenous Influences

Factors associated with environmental conditions such as food availability, population density, light, habitat stability, and seasonal variation in temperature are perceived externally by individuals in a population and delivered to and interpreted by the internal effectors which direct the expression of asexual or sexual reproduction. Nevertheless, it seems that water temperature and food availability play the most important role in this process in sponges. Indeed, it has been showed, that in both tropical and temperate sponges temperature is one of the important factors for the regulation of sexual and asexual reproduction. An increase in the frequency of specimens with buds and increasing of buds per sponge occurs simultaneously with the rapid decrease in water temperature, as was shown for Mediterranean *Tethya citrina*, *T. aurantium*, *Mycale (Aegogropila) contarenii*, Arctic *Polymastia arctica*, and tropical species such as *Cinachyra australiensis* and *Cinachyrella cavernosa*. Sexual reproduction in deep-sea demosponges *Thenaea abyssorum* may be triggered by the vertical flux of particulate organic carbon to this food-limited environment. Development of embryos in *Chalinula ecbasis* is related to particulate food supply.

Numerous attempts have been made to correlate the reproductive activity with the environmental fluctuations. However, correlation does not necessarily indicate the direct causality, and there have been only few experimental studies of sponge reproduction. Clearly, experimental investigations are needed to confirm or refute the conclusions derived from the purely correlative studies.

Sexual Reproduction

The only common feature for all sponge species is the absence of organized gonads, though the spermatocysts, which presented in the choanosome, can be considered as a temporary dispersed gonad.

Male Reproduction

Spermatogenesis occurs in the spermatocysts (spermatocysts) in all sponges, except Calcarea. Spermatocysts are temporary spherical structures, which develop by the transformation of choanocytes of an entire choanocyte chamber (except of the carnivorous demosponges as they have no aquiferous system and choanocyte chambers). The spermatocysts are surrounded by the follicle cells deriving through the transformation of pinacocytes (pseudo-epithelial cells) or archaeocytes. In demosponges cell junctions between the follicle cells are simple (apposition) with no detectable membrane specialization. The follicular cells in the spermatocysts of Homoscleromorpha possess the specialized cell junctions and basement membrane.

According to species, the synchrony of spermatogenesis occurs at three levels: (1) population, as in *Neofibularia nolitangere*; (2) individual, as in *Aplysilla rosea*, *Myxilla incrustans*, *Iophon piceum*, in which all the choanocytes of the choanocyte chambers simultaneously transform into spermatogonia; (3) spermatocyst, as in *Suberites massa*, *Spongia officinalis*.

Except for species that reproduce all year round spermatogenesis appears to occur in a shorter period than oogenesis.

Female Reproduction

Sponge female gametes develop in the choanosome diffusely or, sometimes, in small clusters. This is true for both oviparous and viviparous sponges. No gonads are formed.

Gametogenesis, Fertilization and Early Development

A characteristic feature of gametogenesis in sponges is the origin of the gametes by the direct transformation from the somatic cells - choanocytes or archaeocytes. Otherwise, the stages and cytological features of the gamete development in sponges are similar to those in other animals.

Spermatogenesis

Development of male gametes within a cyst is usually synchronous. In Homoscleromorpha there is a gradient of male gamete maturation within a cyst, a feature they share with the Eumetazoa.

Two different types of somatic cells have been postulated as the source of spermatogonia. These cells are either archaeocytes or, more frequently, choanocytes (flagellated collar cells involved in the particle capture and sponge feeding).

Calcaronea have aberrant spermatozoa: spherical and non-flagellated. (The term “aberrant” is applied to spermatozoa that are very diverse as concerns their external morphology). Spermatozoa of most other sponges belong to the primitive type (ancestral-primitive type): they have a large cytoplasmic volume, several mitochondria and lack the acrosome. Homoscleromorpha and some demosponges from the order Poecilosclerida (*Crambe crambe*, *Crellomima imparidens*, *Asbestopluma hypogea*, and *Hymedesmia irregularis*) have “derived or typical” spermatozoa, characterized by the presence of acrosome, one or two big mitochondria and small volume of cytoplasm.

Sperm of most of the species, except Calcaronea, displays an ovoid or rounded conical head with nucleus. The nucleus could have a shallow recess (*Aplysilla*), kidney-like shape (*Spongia*), cylindrical shape (*Iophon piceum*, *Crambe crambe*, *Crellomima imparidens*), ring-like or helicoidal shape (*Halichondria panicea*), or subspheroidal shape (other species).

The number, size and shape of the mitochondria are very variable, according to the species: one long mitochondrion in *Halichondria*; one, two or three large mitochondria, located in the basal part of the spermatozoon, in *Crambe*, *Aplysilla*, or *Suberites*; and a few to several scattered mitochondria, located in the periphery of the head in the remaining, asymmetrical cytoplasm in *Spongia*, *Lubomirskia*, *Myxilla* or *Anhinoe*.

All primitive and typical poriferan spermatozoa are flagellate, always with a 9+2 axoneme. There are two centrioles.

During spermiogenesis, the Golgi cisternae disappear but in *Suberites*, *Spongia*, *Asbestopluma occidentalis*, and *Petrosia ficiformis* dense proacrosomal vesicles of Golgi origin persist near the nucleus and are considered to possibly represent a rudimentary acrosome.

In all Homoscleromorpha, a fully developed acrosome is presented. A large, conical acrosome has also been showed in the calcaronean *Sycon calcaravis*, and in some of poecilosclerid demosponges (*Crambe crambe*, *Crellomima imparidens*, *Asbestopluma hypogea*, and *Hymedesmia irregularis*).

Though organization of spermatozoa is considered to be a sound taxonomic and phylogenetic character, the presence of acrosome in spermatozoa of Poecilosclerida is at variance with this idea. For instance, *C. crambe*, *C. imparidens* and *H. irregularis* have an acrosome, but another sponge from the same order, *Myxilla*, *Iophon*, and *Anhinoe*, does not. The acrosome is likely to have originated several times in the course of the evolution. Its emergence is associated with the insemination and fertilization type, with the structure of the vitelline envelope and its accessibility for sperm penetration rather than with the taxonomic affiliation or phylogenetic position of the species.

Oogenesis

Two types of the oogenesis can be distinguished in animals – panoistic and meroistic. In panoistic oogenesis, all germ cells have the potential to become the egg cell. In meroistic oogenesis, only a few germ cells become egg cells, while the remaining cells differentiate into the nurse cells (trophocytes) that support the oocytes. Meroistic oogenesis is characterized by the formation of germ cell clusters, where the germ cells are interconnected by stable cytoplasmic bridges.

At the early stages of the sponge oogenesis oocytes have amoeboid-like shape and migrate through the mesohyl, incorporating diverse macromolecules and microorganisms. As the oocyte grows, it takes an oval form and proceeds to vitellogenesis. Usually, yolk-like inclusions are heterogeneous with electron-dense core and less electron-dense periphery. In other species oocyte can also include lipids, rests of digested microorganisms and fibrous or membrane structures. Vitellogenesis in sponges passes via autotynthesis, heterosynthesis or both processes simultaneously.

Autosynthesis is realized by the oocytes using basic precursors received through the oocyte membrane by endo-, pino-, or phagocytosis and followed by intense synthetic activity. Autosynthesis has been described for some oviparous demosponges, for example, *Suberites massa*, *Aplysina cavernicola*, *Tetilla serica*, *Stelletta grubii*, and *Raspaciona aculeata*.

Heterosynthesis involves participation of different types of somatic cells and is typical for most viviparous sponges. Somatic cells either elaborate yolk or its precursors in their cytoplasm, transporting and transferring all these materials to the growing oocytes, or whole cells or their fragments could be phagocytosed by oocytes. These somatic cells (choanocytes, different mesohyl cells) are often referred to as trophocytes or “nurse cells”. However, strictly speaking, sponges do not possess true trophocytes. First, trophocytes are cells developing from the germline in the course of oogenesis. Second, oocytes and trophocytes are connected by cytoplasmic bridges and surrounded by follicular epithelium, which is not characteristic for sponges. Thus, sponge oogenesis is panoistic.

In some demosponges (orders Haplosclerida and Spongillida), vitellogenesis is accompanied by the emergence of a special population of phagosome-rich nucleolated amoebocytes that migrate towards the oocyte and are phagocytosed by it. This is an indication of a higher specialization of oogenesis in these sponges as compared to other demosponge orders.

The combination of both autotrophic and heterotrophic pathways (a mixed pathway) allows the quick development of oocytes and has been described for many demosponges and some Calcareia.

Primitive features of oogenesis and oocyte structure in sponges are the lack of ooplasm segregation and, apparently, of cytoplasmic determinants. Consequently, sponges also lack mechanisms of determination of the axes of the future larva or, in

the case of direct development, the young sponge. In viviparous sponges, another primitive feature of oogenesis is the lack of specialized vitelline envelope. However, oviparous demosponges have a primitive vitelline envelope.

Gametes Resorption

The fate of waste gametes, unspawned or unfertilized oocytes has been investigated in sponges in several cases. Degeneration and resorption of unfertilized oocytes have been reported in some demosponges and calcareous sponges.

The spermatogonia shows phagocytic activity in *Spongia officinalis*. They form pseudopodia around mesohyl bacteria and have cytoplasmic vacuoles containing these bacteria. The follicle cells phagocytose defective elements in the cysts in *Suberites massa*. Somatic cells were found within the spermatogenic cysts of *Chondrilla australiensis*, *Raspaciona aculeate* and *Petrosia ficiformis*. These somatic cells are involved in both elimination of presumably aberrant spermatozoa during spermatogenesis and removal of unspawned sperm. Sperm phagocytosis by the follicle cells in *Asbestopluma occidentalis* may also be directed to achieve an appropriate cell number in spermatogenic cysts as occurs in many other animals.

Fertilization

It is generally accepted that in the oviparous sponges the fertilization is external and in viviparous sponges is internal. However, in some oviparous demosponges, for example, *Cliona celata*, *Chondrosia reniformis*, an internal fertilization occurs.

In the case of external fertilization, spermatozoa and eggs are realized into the surrounding water through the osculum. In some cases, as in the genus *Tetilla* and *Petrosia ficiformis*, after fertilization, a fertilization-like membrane appears externally to the mucous layer of eggs. In oviparous sponges, the extruded eggs or zygotes are often enclosed within a gelatinous material, which hold them together in a mass and binds them to the maternal sponge and adjacent substrate.

An internal fertilization is typical for viviparous sponges. In this case the spermatozoa enter egg-containing individual via the incurrent water system. Then they usually pass through one or more barriers to reach the eggs, which are often scattered in the mesohyl. Nevertheless, male sperm spawning in viviparous sponges has never been documented.

Internal fertilization has been well described only for calcareous sponges from subclass Calcaronea. Fertilization in the Calcaronea is carried out by the so-called carrier cells, which arise from a choanocyte, or more precisely, from an accessory complex cell, which acquired the capacity to capture a spermatozoon.

The carrier cell enlarges two or three-fold after capturing the sperm cell. In *Leucosolenia complicata*, accessory cells directly surrounds the carrier cell probably participating in the transformation of the latter; they actively accumulate inclusions and grow. Fertilization involves two carrier cells surrounding the sperm cell in *Sycon calcaravis*. Inside the carrier cell, the sperm undergoes certain changes and it is referred to as the spermicyst. Its structure is similar in different species. A dense protein capsule covers the spermicyst completely or partly. The nucleus has highly condensed chromatin. Electron-transparent vesicles are situated at the spermicyst's periphery. The spermicyst penetrates into the oocyte by means of one or two carrier cells, which push it into the ooplasm. Inside the oocyte the protein capsule is destroyed and the nucleus decondenses and swells.

Spermicyst penetration triggers the maturation divisions in the oocyte. Extrusion of polar bodies always occurs at the pole oriented towards the choanoderm, though not necessarily at the site of the spermicyst's penetration. After the chromatin in oocyte nucleus decondenses, both nuclei merge.

Embryogenesis and Postembryogenesis Overview

Embryonic development of ovoviviparous and viviparous sponges proceeds in the temporary brood chambers, often referred to as follicles. They are formed at the end of vitellogenesis from flattened cells originating from the choanocytes, amoebocytes, or endopinacocytes. The follicular epithelium later participates in the formation of the aquiferous system canals.

Four main cleavage patterns in sponges are: chaotic cleavage – Homoscleromorpha, most viviparous Demospongiae; radial-like cleavage – oviparous Demospongiae, Hexactinellida; polyaxial cleavage – Halisarcidae (Demospongiae), Calcinea (Calcarea); incurvational cleavage (table palintomy type) – Calcaronea (Calcarea). The spatial position of the blastomeres is usually unstable; divisions either become asynchronous very early or are not synchronous at all from the very beginning.

More complex animals possess embryogenesis comprising distinct stages – cleavage, blastulation, gastrulation, histogenesis and organogenesis. In sponges, these stages, except cleavage, are not so distinct. First, sponges lack the final phase of blastulation. In the end of cleavage, at the stage usually referred to as blastula or morula, the differentiation of the larval cells (external ciliated cells and sclerocytes) begins. Second, the fate of the specialized larval cells (cover cells, skeletogenic cells, etc.) may be different and it is not homologous to the fate of germ layers in Eumetazoa, since Porifera do not have body parts, organs and tissues homologous to those of other metazoans. Besides, there are no mechanisms of the early determination of the cells in the border and internal tissues of the adult sponge. Cleavage in sponges followed by the cell differentiation and migration resulting in a larva or young sponge (in the case of direct development) formation. In poriferan embryogenesis different types of epithelial and mesenchymal morphogeneses occur.

All sponges except the representatives of the demosponges genera *Tetilla* (Tetractinellida) and *Stylocordyla* (Suberitida) have indirect, i.e., larval development. Eight types of sponge larvae have been described: coeloblastula, calciblastula, cinctoblastula,

amphiblastula, disphaerula, hoplitomella, parenchymella and trichimella. In general, there are two principal larval constructions in sponges: hollow single-layered larvae (coeloblastula, calciblastula, cinctoblastula, amphiblastula) and two-layered larvae without cavity (parenchymella, hoplitomella, trichimella). Disphaerula occupies a morphologically intermediate position. All the larval types, except hoplitomella, are characterized by a distinct anterior-posterior polarity. Externally, it may be expressed in the body shape, the ciliation character at different poles and the unevenness of colour. At the histological level, the polarity is expressed in the distribution of various cell types, in orientation and position of spicules (parenchymellae and trichimella) and in unequal concentration of endosymbiotic bacteria (cinctoblastula).

Metamorphosis is a short stage of the post-embryonic development during which the larva undergoes radical morphological and physiological changes due to its transition to the attached adult stage. Some structures, usually the larval or provisional ones, disappear, the others, that were rudimentary, rapidly complete their development. Morphogeneses, accompanying sponge larvae metamorphosis could be epithelial type, epithelial-mesenchymal transitions or mesenchymal-epithelial transformations depending on the larval structure. The main feature of the metamorphosis of the sponge larvae is the acquisition of the sponge Bauplan, which is mainly represented by the aquiferous system. The first adult structure to be formed *de novo* is the exopinacoderm, which isolates the young sponge from the milieu. Later steps include organization of the choanocyte chambers and the water current canals, the opening of the ostia and osculum and the acquisition of the adult skeleton elements.

Larval metamorphosis usually results in a mono-ocular individual, whose aquiferous system is different from that of the adult sponge. In the Calcarea such a young individual has the aquiferous system of the asconoid type and is called the olynthus; in the Demospongiae and the Homoscleromorpha it has the aquiferous system of the leuconoid or syconoid type and is called the rhagon.

Sexual Behaviour

In sessile animals like the sponges, the field of phenomena related to behaviour, and consequently to the behaviour associated with reproduction, is very limited. The most studied aspects are those concerning the release of gametes.

In oviparous demosponges spermatozoa and eggs are shed into the excurrent canals and discharged through the oscula. The mass release of spermatozoa detected as a white 'smoke' is a simultaneous shedding of the spermatozoa by many individuals in a local population. This phenomenon suggests a regulation mechanism of spermatozoa release, which could be related to the diel light/dark regime. A synchronicity has been observed also for the egg release in oviparous demosponges. The synchronous release of eggs is highly correlated in seasonality and lunar phase from year to year and the oocytes release is often synchronous with that of sperm throughout local populations, as was shown for *Hemectyon ferox*.

In some sponges, living within relatively stable conditions, emission of spermatozoa is closely correlated with the lunar phase.
